Elan 1.7 Manual

Manual for the Elan Programming Environment
for personal computers

November 16, 1998

C.H.A. Koster
Th.P. van der Weide

Elan is an educational programming language for learning and teaching systematic programming. The Elan project group at the University of Nijmegen in the Netherlands has developed an educational programming environment around Elan. This document is the manual for that programming environment which is herewith made freely available to the international computing community for educational purposes. No commercial use is allowed without written prior consent from the authors.

Introduction

About this manual

This is the user manual for version 1.7 of the Elan Programming Environment developed at the university of Nijmegen in the Netherlands, which is currently available on various UNIX machines, MS-DOS machines, Apple Macintosh, Atari and Amiga.

This manual gives a short description for the user of the Elan Programming Environment. It assumes the reader to have a good knowledge of programming in algorithmic languages.

About the language

Elan was developed in 1974 by a group at the Technical University of Berlin (see [1]) as an alternative to BASIC in teaching, and approved for use in secondary schools in Germany by the "Arbeitskreis Schulsprache". It is presently in use in a number of schools in Western Germany, Belgium, the Netherlands and Hungary for informatics teaching in secondary education, and used at the university of Nijmegen in the Netherlands for teaching systematic programming to students from various disciplines and in teacher courses.

Elan was especially designed for one specific application area: the teaching of systematic programming. The language is not oriented towards general usage or towards other application areas. It can be seen as a didactic framework embodying a number of ideas about systematic programming and supporting, through specific language mechanisms, the learning of the two complementary programming styles

- Top-Down programming, using suitable control structures and data structures, refinements, and shorthand declarations; and
- Bottom-Up programming, using procedure-, operator- and type-declarations in conjunction with encapsulation and interfaces;

as well as a number of related programming styles (recursive programming, modular programming, syntax-directed programming).

Elan is a typical algorithmic language in the ALGOL family, more related to ALGOL68 than to PASCAL. The language is not an experiment in language design; both syntactically and semantically it is quite conventional. Its control structures are the conventional Dijkstra structures, in conjunction with a leave-statement. Its data structures are limited to the (fixed size) row and structure - not as rich as ALGOL 68 but much simpler due to the absence of the reference concept.

In order to support the learning of systematic programming, it stresses instead the use of abstraction mechanisms. Its striking features are:

- The *refinement* as a syntactic construct for the support of Top-Down programming;
- Declarations for recursive and polymorphic *types*;

- Generic and polymorphic *procedures* and *operators* for the support of Bottom-Up programming; and
- *Packets with explicit interfaces* for the support of modular programming.

About this implementation

The Elan Programming Environment is a portable environment. On any machine, it will behave as described here, apart from some frills and idiosyncrasies typical for the machine used (such as self-explanatory pull-down menus, etc.). Therefore it allows a high degree of machine independence in producing courseware.

The simplest industry standard PC, with at least one floppy drive and 256 K of memory, is sufficient for its use. For people having even smaller computers (like Apple II, Commodore 64 and Philips P2000), implementations of the smaller Elan-0 Programming Environment are available from

Katholieke Universiteit Nijmegen,
Informatica/Elan project,
Toernooiveld 1,
6525 ED Nijmegen, the Netherlands.
Email elan@cs.kun.nl

It should be realized that the present version 1.7 is an intermediate product. It is relatively slow, with severe limitations on the available memory. A more complete implementation of Elan is in preparation, including a compiler back-end. In the mean time the present version should be sufficient for most teaching purposes - and it will only get better.

Any problems or requests about the Elan Programming Environment can be sent to the above address. Note however, that the University of Nijmegen gives no warranty, and does not promise to correct errors reported in this version.

Contents

Chapter 1

An example-session

This example session introduces you in a hands-on fashion to the use of the Elan Programming Environment. By following the session to the letter you obtain a quick tour of most of its facilities. If you use a later version than 1.7.2, you might notice some minor differences.

In this chapter we will mark output from the Elan Programming Environment with a line in the left margin; the input of the user is given without such a mark. The *cursor* will be depicted as ▯. In input from the user we will explicitly indicate the "return" or "enter" key by `<RET>` and the "delete" key by `<DEL>`. The `<BREAK>` is a special key to notify the Elan Programming Environment to stop whatever it is doing. Its realization may well be different for the various implementations (usually CNTL-C, BREAK-key, special buttons, etc.; read the documentation which is distributed on the floppy disk with the software).

cursor

return key

delete key

break key

1.1 Starting...

After you have booted and started the Elan Programming Environment, the following identifying message appears on the screen:

```
|       Elan Programming Environment
|       version 1.7.2
|       Copyright KUN, Aug 1989
|
|
|       Free space: 16349
|
|       PACKET standard library
```

Immediately underneath you will find the *focus*, i.e. the name of the refinement that is the current focus of interest. The default focus is

focus

```
|       program ?▯
```

The question mark means that `program` is not the name of a known refinement, i.e. it has not yet obtained a meaning. At the bottom of the screen, on the *status line*, you find the message

status line

```
|                                 Command, please...
```

indicating what is expected from you. By giving the *help-command*

help-command

```
h
```

you are shown on the status line a list of the applicable commands. The commands are described in 4.3. The help-command serves only as a reminder.

1.2 ... and stopping

quit-command

Once having learned how to start you must learn how to stop, just like the apprentice sorcerer. You can stop the programming environment by giving the *quit-command*

```
q
```

where upon you are asked for a *confirmation*

```
| program ? QUIT ?
```

confirmation

The possible answers (as elicited by the help-command) are `y` and `n`. Upon answering

```
n
```

the quit-command does nothing and the confirmation message disappears from your screen. Upon answering

```
y
```

the programming environment halts and returns control to the system on which it is running. Upon quitting, the program that is then in memory is forgotten (but of course all programs that have been written to a file are retained).

1.3 Reading a program

As an example we will read, execute and modify the program called `race`, which can be found on the distribution diskette containing the Elan Programming Environment. We make sure the floppy disk is inserted and give the *read-command*

read-command

```
r
```

The programming environment reacts by asking

```
| Name:
```

The status line now says

```
|                                   Reading...
```

We now have to indicate the name of the file. Assuming that the file `race` from the distribution diskette is available, we type in

```
race<RET>
```

Notice that this time we have to give a `<RET>` at the end in order to indicate that the name is completed. Since commands consist of one single letter they do not need such an indication. The names of the refinements of the program pass over the screen. Upon completion of the reading, the interpreter gives a *view*, a list of all known refinements and an indication of the remaining memory space. The view shows the calling hierarchy of refinements.

view

```
|       Free space:  16021
|
|       PACKET standard library
|
|       LET no of horses
|       program
|       | start horses
|       | | display title, put horse at startpos,
|       | | mark start of track, mark end of track
|       | choose horse, move horse, finished, display winner
|
|       program:
```

The status line again says

```
|                                   Command, please...
```

This view you now have can also be obtained by giving the *list-command* list-command

```
l
```

1.4 Inspecting and executing a refinement

Your current focus, the refinement `program` has, by the reading, obtained a value, which can be displayed on the screen by means of the *show-command* show-command

```
s
|       program:
|         start horses;
|         REP
|           choose horse;
|           move horse
|         UNTIL finished
|         ENDREP;
|         display winner.
|
|       program:
```

The focus is still `program`, but now its meaning is defined, as is shown by the fact that it is followed by a `:` instead of a `?`. We can execute the program with this refinement as *root* by giving the *execute-command* root execute-command

```
x
```

Just try it, and see what happens.

1.5 Shifting the focus

In order to inspect or execute another refinement, e.g. `start horses`, we have to change the focus by means of the *focus-command*. focus-command

```
f
|       Name:
        start horses<RET>
|       start horses:
```

We can now inspect this refinement by means of the show-command. The focus-command (`f`) can be used to focus on any name, be it already defined or unknown. For focussing on known names, a *shorthand* mechanism exists: we may replace the last part of the name by a `*`, e.g. abbreviated name

```
start h*<RET>
```

Notice that if we had given a shorter part of the name, e.g. `start*<RET>` we would have focussed on the object `start conversion` instead.

1.6 Modifying a refinement

We will now modify one of the refinements of the program. We are focussed on `start horses` and give the show-command

```
        s
|       start horses:
|         INT CONST start pos :: 12;
|         INT CONST end pos :: 50;
|         ROW no of horses INT VAR horse;
|         display title;
|         INT VAR i;
|         FOR i FROM 1 UPTO no of horses
|         REP
|           put horse at start pos;
|           mark start of track;
|           mark end of track;
|         ENDREP.
|
|       start horses:
```

edit-command

We wish to change the `50` in the second line of the body of the refinement into `70`. To that end we give the *edit-command*

```
        e
```

The same text appears, with on the status line

```
|                                   Input, please...
```

cursor keys

By means of the *cursor keys* (marked with arrows) we move the cursor to the right position, strike out the `5` by means of the `<DEL>`-key and insert a `7` instead. We then strike the `<RET>`-key to indicate that the modification is complete.

We now want to see what effect this modification has on the execution of the program. We first have to focus again on the root

```
        f
|       Name:
```

We make use of the shorthand mechanism

```
        prog*<RET>
|       program:
```

By giving the execute-command we can verify that the race track has indeed become a little longer now.

1.7 Saving a program

write-command

We can save the program to a file by means of the *write-command*

```
        w
|       Name:
```

On the status line the message

```
|                                   Writing...
```

appears and we have to choose a name for the file, e.g.

```
longrace<RET>
```

prompt After some time we again obtain the *prompt*

```
program:
```

1.8 Clearing the memory

We can clear the whole memory by means of the *clear-command* clear-command

```
c
```

whereupon the interpreter asks for confirmation

```
program: CLEAR ?
```

The two possible answers are

```
n
```

whereupon the command has no effect, and

```
y
```

which causes the interpreter to come back to its initial state with an empty memory.

1.9 Directory of files

The programs saved in this fashion can be read back from file into memory by means of the read-command. Since we may in time forget the names of our files, it is possible to get a *directory*, i.e. list of file names. We obtain this by a somewhat roundabout way, viz. by directory trying to read a file that is definitively not there, e.g.

```
r
Name:
rrrrr<RET>
```

We can now inspect the directory to decide what is the name of the file we want to read.

1.10 Entering a new program

It is of course possible to input a program from scratch. It is not at all advisable to program whilst sitting in front of the computer screen, so we assume the reader to have written the following little program, that he now wishes to enter into the computer:

```
my first program:
  read two numbers;
  print their sum.

read two numbers:
  read first number;
  read second number.

read first number:
  INT VAR first;
  put ("First number = ");
  get (first);
  line.
```

```
read second number:
  INT VAR second;
  put ("Second number = ");
  get (second);
  line.

print their sum:
  line;
  put ("Sum = ");
  put (first + second).
```

root

After starting the Elan Programming Environment, first focus on the name of the refinement which is to serve as the *root* of the program. Since it is rather hard to change the name of the root once it is chosen, we have to choose it with care.

```
        f
|       Name:
        my first program<RET>
```

The prompt tells us we have focussed successfully.

```
|       my first program ?
```

We now supply a definition for the root by means of the editor.

```
        e
|       my first program:
|
```

We type:

```
        read two numbers;print their sum.<RET>
|       my first program:
```

pretty print

The prompt now tells us that the root is a refinement. Notice that we need not take particular pains to make a nice layout, because the *pretty printing* function of the show-command will standardize the layout anyway.

```
        s
|       my first program:
|         read two numbers;
|         print their sum.
|
|       my first program:
```

1.11 Automatic guidance of input

input guidance

The prospect of entering the remaining refinements one by one, by first focussing on their name and then using the editor, is rather forbidding. Luckily there is a possibility to avoid all the effort of focussing and retyping names: we can be guided by the Elan Programming Environment, so that we have to input only the bodies of the refinements.

We are focussed on the root and try to execute it.

```
|       my first program:
        x
```

Immediately we are warned of the fact that the first refinement is unknown.

```
|       read two numbers
|                                read two numbers

|       Can't identify           Backtrace command, please...
```

We are now in backtrace-mood, and give the edit-command

```
        e
```

The Elan Programming Environment responds by

```
|       read two numbers:
|
```

After having entered the body, we return to the root of the program, which we try to execute again.

In this way, we are made to enter one refinement at a time, until the program is complete. This guidance during input allows us to type most refinement names only once, thus alleviating one of the drawbacks of Top-Down programming and encouraging the use of meaningful identifiers.

1.12 Entering procedures and types

Once you reach the stage of Bottom-Up programming, you must learn how to input your own types, procedures and operators. You do this by first focussing on any name (for instance the name of the type or procedure you want to enter), give the edit-command and then enter the declaration followed by a semicolon.

Some examples. Let us first enter a procedure `new number`.

```
        f
|       Name:
        new number<RET>
|       new number ?
```

The Elan Programming Environment takes this for a refinement name.

```
        e
|       new number:
|
```

We edit the text on the screen until we have obtained a complete procedure declaration, followed by a semicolon.

```
INT PROC new number:<RET>
  INT VAR n;<RET>
  get(n);<RET>
  n<RET>
ENDPROC new number;<RET>
```

We can now see from the prompt that our focus is a procedure

```
  INT PROC new number
```

As a second example, let us enter a type-declaration.

```
        f
|       Name:
        COMPL<RET>
|       COMPL ?
```

We massage this text on the screen into the type-declaration we want to have.

```
        TYPE COMPL = STRUCT (REAL re, im);<RET>
|       TYPE COMPL
```

Do not forget the semicolon at the end.

The order of refinements, type-declarations, procedure-declarations and operator-declarations is free, but the first refinement which is entered becomes the root of the program.

1.13 Inspecting the standard library

By means of the focus- and show-command we can inspect not only the definitions which we have entered ourselves but also those of the standard library. In 4.2.4 the mechanics of this facility are explained. We will use it to look at the available addition operations.

```
        f
|       Name:
        +<RET>
|       FROM PACKET standard library
|         TEXT OP + (TEXT CONST a, b)
|         REAL OP + (REAL CONST a, b)
|         INT OP + (INT CONST a, b)
|         REAL OP + (REAL CONST a)
|         INT OP + (INT CONST a)
```

We observe there are several definitions, of which the first one is presently the focus. By means of the (repeated) use of the *next-command*

next-command

```
        n
```

or the *up-command*

up-command

```
        u
```

The cursor keys might serve the same purpose. We can make any of these definitions the focus. We can inspect it by giving a show-command

```
        s
|       PACKET standard library
|       TEXT OP + (TEXT CONST a):
|         CODE 88
|
|       ENDOP +
|
|       FROM PACKET standard library
|         TEXT OP + (TEXT CONST a, b)
|         REAL OP + (REAL CONST a, b)
|         INT OP + (INT CONST a, b)
|         REAL OP + (REAL CONST a)
|         INT OP + (INT CONST a)
```

which does not really make us much wiser.

generic name

A name with more than one definition (such as `+` or `put`) is called generic.

1.14 Packets

In a classroom situation it will not always be the case that a complete program is written from scratch. Rather the teacher will supply a packet of definitions, or even a complete program that the pupils have to use. For this reason, the Elan Programming Environment has a simple facility for reading packets.

By a *packet* we mean a collection of declarations that the pupils may use in a program of their own without the necessity to type them in. packet

For reading these, a variant of the read-command has been introduced, the packet-command (`p`), which has the property that it keeps the contents of the packet practically invisible: the pupil can inspect but cannot modify or delete them. When, by accident, reading a normal program with this packet-command the program will be read as if a read-command was issued.

1.15 Reading a packet

The program `charles` is a packet, not a standard program, since it is protected by a PACKET encapsulation from which it *export*s some definitions. This gives us the opportunity to add our own program, in which all the exported definitions of the packet can be used. The packet as it were extends the language with a number of concrete algorithms. export

In order to use this packet `charles` we first read it with the packet-command. Then we read the packet `environ` in the same way. Finally we read the program `morning` by means of a read-command and give the execute-command. Only the definitions of this last program can be modified or deleted in the usual way.

A packet usually contains definitions that are exported and definitions that are used only within the packet. The *local* definitions can only be shown by stepping into the packet using the *into-command*. The exported definitions can be focussed on everywhere, it doesn't matter if you are inside the packet or not. They are, however, not shown by the list-command if your focus is outside the packet. local into-command

Below an example using the `PACKET standard library`. First we focus on the name `standard library`.

```
        f
|       Name: 
        standard library<RET>
|       PACKET standard library
```

Now we can step into the packet `standard library`.

```
        i
|       PACKET standard library
|
[       inventory list of packet     ]
|
|       ENDPACKET standard library
|
|       PACKET standard library
|       No packet root.
```

Now you can focus on all the definitions within the packet and inspect them. Use the *out-command* to step out of the packet. out-command

```
        o
|       Free space: 16349
|
|       PACKET standard library
|
|
|       program ?
```

1.16 Conclusion

In this quick tour we have missed many important aspects of the programming environment, such as

- deleting a refinement, object, type or generic operation;
- the incremental syntax check during input of new refinements;
- the backtrace facility for semantic errors;
- the edit-on-the-fly upon detection of syntactic or semantic errors;
- the trace facility;
- the packet write facility.

We have not discussed useful tricks, such as

- how to change the name of a refinement (take it into the editor, edit its name, delete the original);
- how to inspect the value of a variable or constant after execution of the program (focus on its name and show it);
- the use of the `<BREAK>`-key to halt execution or input.

Since these are all consequences of things described in Chapter 4, it may be useful to read that chapter.

Chapter 2

A brief introduction to Elan-0

Elan-0 is a small subset of Elan, which is intended for learning systematic Top-Down programming. The best way to get acquainted with Elan and to appreciate the programming style it aims to support is to start with the Elan-0 subset.

This chapter of the manual is intended for readers who already have some experience in programming in an algorithmic language. Notice that a careful distinction is made between remarks which pertain to Elan as a whole and remarks confined to the Elan-0 subset. In chapter 4 the syntax of the full language (with the exception of packets) can be found, which is available in the Elan Programming Environment.

2.1 Some concepts of programming languages

The following terminology and concepts are applicable to any programming language, but in particular to Elan, since they lie at the heart of its design. Readers not interested in philosophy may skip this section.

2.1.1 Entities

A program is a text, viz. the formulation of some algorithm, expressed in a programming language. This text obeys the syntax of the programming language, and according to that syntax consists of a nested collection of constructs. Among these constructs, three general classes can be distinguished: *algorithms*, *objects* and *types*, which have the distinction that they can be denoted by names. The program text consists of such *entities*, glued together by control structures, data structures and further composition mechanisms such as expressions and functional application.

2.1.2 Elementary and composed entities

An entity which is denoted by a name we will term *elementary*; the others are *composed*. It may very well be that a composed entity at one place of the program obtains a name, by means of a *declaration*, and at other places of the program is denoted by that name. Such a declaration serves as an abstraction mechanism. Besides a shortening of the program, this naming of entities allows the introduction of various *levels of abstraction*.

2.1.3 Abstract and concrete entities

Some elementary entities belong to the language and are available without further effort by the programmer, with their specific semantics. These we will term *concrete*. Others we will term *abstract*: they are constructed by the programmer and abstracted by means of a

declaration. We might define programming along these lines as the construction of abstract algorithms.

2.1.4 Composition mechanisms

In the design of an algorithm a programmer should not try to express it in all detail at once. Instead, the programmer should split it into major parts which can be refined in a stepwise fashion down to the elementary entities belonging to the programming language. Algorithms are thus composed of other algorithms which in their turn are either composed or elementary.

Particular composition mechanisms for the algorithms on the one hand, and the objects and types on the other hand, are termed *control structures* and *data structures*, respectively.

2.1.5 Where does Elan fit in this taxonomy?

Traditionally, composition mechanisms have been seen as the central mechanisms in systematic ("structured") programming. Elan has rather conventional control structures and relatively simple data structures. In contrast, in Elan the abstraction mechanisms are seen as the central issue in any programming methodology and consequently highly developed.

The Elan Programming Environment further stresses this view by making the definition of abstract algorithms (refinements) the basis for the development and manipulation of programs. It considers a program as a collection of refinements, rather than one text.

2.2 The notation of algorithms

2.2.1 Names of algorithms

Names are either the names of concrete algorithms, which means that they are predefined in the Elan Interpreter, or they are introduced by the programmer by the definition of abstract algorithms using refinements. Here we explain their formation rules.

Names for abstract algorithms can be freely invented. Such a name has the form of an *identifier*, consisting of a leading (lower case) letter, followed by letters, digits, and possibly embedded spaces. The latter serve to enhance the readability of programs. In contrast to full Elan, such spaces in Elan-0 are considered significant and are part of the name. Some examples:

```
find upper limit
word occurs on this page
```

Names shall be chosen such that they express concisely *what* is done by an algorithm, not spelling out in detail *how* it is performed. Inventing suitable names is a non-trivial task and needs experience which can be gained only by the study of good examples, exercises, and by the contemplation of programming problems.

2.2.2 Control structures

The first step towards a precise description of algorithms is the use of a collection of stylistic patterns for connecting together the algorithmic steps performed in the execution of programs. These patterns are called *control structures*. Elan-0 knows the following:

- sequence;
- repetition;
- choice.

The forms available in Elan are also available in most other programming languages. Elan uses a notation with keywords written in upper case. They will be introduced by way of examples in the next subchapters.

2.2.2.1 Sequence

The sequential execution of the steps of an algorithm is denoted by placing a semicolon between them.

```
read the current page ;
turn page over ;
read the current page
```

These are the names of three abstract algorithms to be executed one after the other. The semicolon is a *separator* between them (not a terminator), and can be read as "and then".

We call such a sequence a *paragraph*, and its constituents *units*. The example paragraph above contains 3 such units and its execution consists of the execution, in that order, of the three units. In this way the *effect* of the paragraph is the composition of the effects of its units. The *value* of a paragraph (if any) is the value of its last unit.

2.2.2.2 Repetition

Repetition can be expressed in a number of ways. An important paradigm of repetition is the while-loop, e.g.

```
WHILE
  the word does not occur on this page
REP
  look at the following page
ENDREP
```

The *condition* between `WHILE` and `REP` is a unit which, upon evaluation, yields a truth value (true or false).

The paragraph between the keywords `REP` and `ENDREP` is executed only if the condition yields true. After the execution of the paragraph (the "loop-body") the condition is evaluated again, and accordingly the loop-body may be executed repeatedly. The execution ends as soon as the condition upon evaluation yields false. For those who prefer more readable keywords, `REP` may be also written as `REPEAT`, and `ENDREP` as `ENDREPEAT`.

```
WHILE
  the sun is shining
REP
  have a drink ;
  sing another song
ENDREP
```

In this kind of repetition a test of applicability is performed before each cycle ("pre-checked-loop"). If in this example it is rainy, the loop-body is never executed, and you have to stay sober.

For cases where there is always something to be done first, and checked for repetition afterwards ("post-checked-loop") Elan has the following complementary repetitive construct:

```
REP
  drink a glass of tea with rum ;
  sing a christmas carol
UNTIL
  it stops snowing
ENDREP
```

In this case the condition which stands between UNTIL and ENDREP is executed after each execution of the first paragraph, the repetition continues if the condition yields false and stops if the condition yields true.

For cases where the number of repetitions is known in advance, Elan offers a "counting-loop", also called for-loop.

```
FOR i FROM min UPTO max
REP
  tally i th entry
ENDREP
```

The units min and max yielding integers are evaluated once at the beginning of the for-loop. The controlled integer variable i gets the value of min. As long as i is less or equal to max, the loop-body between REP and ENDREP is executed, followed by an increment of the "loop-variable" i by one. Within the loop-body i may be used, but not assigned to. Its value is undefined after the execution of the for-loop.

In case you want to count not upwards, but downwards from a larger value to a smaller one, there is a variant of the counting-loop:

```
FOR nr FROM stock DOWNTO minimum
REP
  sell one
ENDREP
```

In this variant, nr is counted down from stock to minimum. If stock was already below minimum, then the loop-body is not executed.

In case the value of the from-part is one and the controlled variable is of no interest, the for- and from-parts may be left out, leading to the shorter form

```
UPTO 20
REP
  hit him over the head ;
  pick him up
ENDREP
```

A later section will demonstrate the use of the counting-loop in processing rows of data elements.

2.2.2.3 Choice

Choosing between two alternatives depending on a condition is written in Elan as:

```
IF condition
THEN part for condition true
ELSE part for condition false
FI
```

If the condition evaluates to true, then the paragraph between THEN and ELSE (the "then-part") is executed, and the rest up to the FI skipped. In the contrary case, the then-part is skipped, and the paragraph between ELSE and FI is executed (the "else-part"). The keyword FI may also be spelled as ENDIF.

This primary form of choice has two variations for common needs. If there is nothing to do in the else-part, then the choice can be simplified by leaving out the else-part:

```
IF it looks like rain
THEN take the umbrella with you
FI
```

In case the weather is fine you do nothing (`ELSE do nothing` was omitted). For decision cascades like

```
IF condition 1
THEN action 1
ELSE
  IF condition 2
  THEN action 2
  ELSE
    IF
      ...
    FI
  FI
FI
```

Elan offers another variant of the choice construction:

```
IF condition 1
THEN action 1
ELIF condition 2
THEN action 2
ELIF
  ...
ELSE action for all conditions above failing
FI
```

Also in this case, an empty else-part may be omitted.

2.2.2.4 Control structures yielding a value

The execution of a paragraph or a choice can also *yield* a value, namely that of the last unit executed. The paragraph

```
compute sum of integers 1 to 10 ;
that sum + 1
```

suggests that first the integers 1, 2, ... 10 are summed up, resulting in a value of 55, and then the value 56 is yielded by that paragraph. If the last unit of a paragraph yields a value, then the paragraph as a whole yields that value.

In case of a choice, the value yielded is that of the paragraph in the then-part or in the else-part, depending on the condition. These values must have the same type. As an example, the unit

```
IF a < b THEN a ELSE b FI
```

yields the smaller of the two integer values `a` and `b`. Repetitions cannot yield a value.

2.2.3 Refinement

The most striking construct of Elan is the *refinement*, a simple mechanism for defining abstract algorithms which forms the basis for the *Top-Down* programming style, which can be summarized:

> "A program is developed by first giving a rough but potentially correct formulation composed of abstract entities. Thereupon each of these abstract entities is similarly defined, in terms of other abstract and concrete entities, until at last all necessary abstract entities have a suitable definition."

A refinement gives a name to a paragraph, and looks like

```
name: paragraph.
```

Executing the name of a refinement means executing its constituent paragraph (its *body*). The value of the refinement is the value of its body.

In distinction to procedures (which could also in principle be used as refinements) refinements may appear in any order, and may in particular appear after any invocation of the refinement. Refinements can not have parameters, in order to keep the "visual overhead" in their definition and application to a minimum. A refinement does not form a separate scope of naming. Therefore it is possible to put a declaration in one refinement and use it in another. For these reasons, refinements are better suited than procedures for capturing the "fleeting abstractions" in programming.

In Elan-0, a program consists of one or more refinements, where the first refinement is the *root* of the program. Such programs correspond to procedure-bodies in full Elan.

2.2.4 Leave-statement

Elan has a special mechanism for terminating the execution of a particular refinement, which looks like

```
LEAVE refinement name
```

This mechanism can in particular be used to terminate repetitions from the inside.

Although it looks much like the infamous goto-statement, the leave-statement is very different: It does not allow arbitrary continuation of program execution at some other part of the program with all its known dangers, but completes the execution of an algorithm. For this reason, you may name in a leave-statement only a refinement of whose execution the execution of the leave-statement is part. It is even possible to leave a refinement with a value, by

```
LEAVE refinement name WITH expression
```

This causes the refinement with that name to be left, yielding the value of the expression.

2.3 The notation of objects

Algorithms to be executed on a computer do not work on thin air, but need objects to operate on. In this chapter we describe what kinds of objects are available in Elan-0, and what are the basic algorithms to handle them. Objects occur in programs in two forms:

- Elementary objects are variables and constants which come into life by the execution of *declarations*;
- Composed objects are the *expressions*. Expressions are a convenient notation for the computation of values. A particular kind of expression are *denotations*, a way of writing down values in the program text.

2.3.1 Declaring objects

In Elan all elementary objects must be declared. This declaration may occur at any place in the program, provided there is only one such place, and in executing the program the declaration of an object precedes all its applications. Thus there is no necessity to collect all declarations at the head of the program but declarations can appear at the place where they are first needed. A declaration may even occur within the body of a loop.

A declaration is a unit which introduces an elementary object with four attributes:

- a type;
- a name;
- a value, which may be undefined; and
- an access right.

A declaration makes the name of the object known throughout the whole Elan program.

2.3.1.1 Names

The names of objects are identifiers, just like those for algorithms, and may be chosen freely, as long as they differ from the names of any other entities in the program.

2.3.1.2 Types

The type of an object serves two purposes:

- It expresses what operations can be applied to the objects in question. In a way, it controls that apples cannot be added to oranges;
- It determines the internal representation of values in the computer's memory.

There are four basic types in Elan, denoted in program texts by the keywords:

- `INT`
  integral numbers in the range -2147483647 to 2147483647;
- `REAL`
  real numbers in a precision of 14 decimals;
- `BOOL`
  truth values, true and false; and
- `TEXT`
  sequences of characters.

Furthermore, objects of any type can be composed into one dimensional rows. These composed types are discussed in the subchapter on rows.

2.3.1.3 Values

Since values of the various types are kept within the memory of the computer, little can be said about them. Knowledge of their internal representation is not at all necessary to understand their relevant properties. It should be noted that the Elan programming environment detects and reports the manipulation of undefined values, e.g. an attempt to use the value of an uninitialized variable.

2.3.1.4 Access attributes

The access attribute of an object is either `VAR` or `CONST` and the objects are correspondingly classed as variables and constants. The value of a variable can be changed by an assignment, whereas the value of a constant cannot.

2.3.2 Declarations

A variable declaration may give an initial value to a variable,

```
INT VAR middle :: ( 1 + max ) DIV 2
```

otherwise its initial value is undefined, as in

```
VAR x
```

Two or more variable declarations can be combined into one unit

```
VAR left pointer :: 1 ,
    right pointer :: max ,
    middle pointer
```

A constant declaration must give an initial value to a constant

```
INT CONST small :: 4711 ;
TEXT CONST capital :: "monaco"
```

Each execution of a declaration causes a new elaboration of the initialization. In this way a constant may have a different value after each declaration executed. The term "constant" is therefore somewhat misleading: its value is not changeable by an assignment, therefore it is constant over part or all of the program.

2.3.3 Denotations

Values of basic type can be written down (denoted) in a program text by denotations:

- `INT`
  Natural numbers can be written as a sequence of digits, e.g. `3`, `198`, `10000` are all three valid `INT` denotations.

  Negative numbers can be written as expressions consisting of a monadic minus operator and an `INT` denotation, e.g. `-57`, as you might have suspected.

- `REAL`
  Elan admits the conventional fixed point and floating point representation for (approximations) of real numbers, like `3.1415269`, `1.3e-8`.

- `BOOL`
  There are only two values for truth values, which are denoted by the constants `TRUE` and `FALSE` respectively. People allergic to capital letters may use the concrete standard constants `true` and `false` instead.

- `TEXT`
  Text denotations consist of sequences of characters enclosed in quotation marks, e.g. `"Hello world!"`
  All printable characters of your computer are allowed within text denotations. If a quote character is to appear in a text denotation, then it has te be doubled, e.g. `"He said ""Don't!"""` The empty text consisting of no characters is denoted by `""`.

2.3.4 Expressions

An expression in Elan is composed in the conventional fashion out of operands, monadic operators and dyadic operators with brackets to indicate grouping. An operand may in Elan-0 be the name of an object, a denotation, a subscription, an invocation of a refinement or the call of a standard procedure. The priority of operators, from high to low, is as follows:

- the monadic operators `+`, `-`, `NOT`, `HEAD`, `TAIL`, `LENGTH`
- `*`, `DIV`, `MOD`
- dyadic `+`, `-`
- `=`, `<>`, `>`, `>=`, `<`, `<=`
- `AND`
- `OR`
- `SUB`
- `INCR`, `DECR`, `CAT`
- the assignment operator `:=`

2.3.5 Assignments

The assignment is a unit of the form

```
var := expr
```

where `var` is a variable of some type and `expr` an expression of the same type.

The assignment serves to change the value of the variable. It is executed by first executing the expression and then making its value the new value of the variable. The value of all other variables remains unchanged. Thus the assignment

```
x := x + 1
```

which can be read as "x becomes x plus one" does not mean that in some curious way `x` becomes equal to itself plus one, but rather that first the sum of the present value of `x` and one is computed and then that value is made to be the new value of `x`.

2.3.6 Composed objects: rows

In Elan-0 the only composed objects are (one-dimensional) row-variables and row-constants. A declaration for a row-variable looks like

```
ROW 5 INT VAR weight
    |   |   |     |____name of the variable
    |   |   |_____access attribute
    |   |_____type of each element
    |_____number of elements
```

After this declaration, the row-variable `weight` has 5 elements, numbered from 1 to 5. Each element has an (as yet undefined) value of the type `INT`.

The subscription

```
row [ i ]
```

denotes its i-th element provided the value of the expression i (the *index*) is between one and the number of elements. A subscription of a row-variable has the access attribute VAR, so it can be assigned to, e.g.

```
weight [ i ] := 144
```

After this assignment, the element whose index is equal to the value of i, which must be in the range 1 to 5, is equal to 144. Similarly, a row-constant can be declared like

```
ROW 5 INT CONST first 5 primes ::[ 2, 3, 5, 7, 11 ]
```

The construct with the square brackets in this example is a *row-display*, which acts as a denotation for a row. As with other constant declarations, the initialization (with a row-display or another row) in a row-constant declaration is obligatory. A subscription from a row-constant has the access attribute CONST, so it can not be assigned to.

Apart from the possibility of manipulating individual elements of a row, it is also possible to deal with the row as a whole, e.g. in the assignment

```
weight := first 5 primes
```

In assignments and initializations, the number of elements in the left and right hand side must match. The elements of a row can in their turn be rows again, with a declaration like

```
ROW 10 ROW 20 INT table
```

and a subscription like

```
table [ i ][ j + 1 ]
```

provided, of course, that 1 <= i <= 10 and 1 <= j + 1 <= 20.

2.3.7 Synonym declarations

In Elan the number of elements ("upper-bound", "cardinality") in a row declaration must be given by a denotation, that is, it can not be dependent on the execution of the program. A row therefore has a statically fixed number of elements. (This is something of a nuisance but reflects the fact that rows in Elan do not serve like arrays in other languages. They are intended to be somewhat inflexible and primitive, and more convenient data types should be built upon them. In a beginners environment, their simplicity is an advantage).

Since this upper bound may have to appear in many places in a program, a mechanism is available which allows the naming of denotations. Such a *synonym declaration* looks like

```
LET max = 5
```

which causes the identifier max to stand for the denotation 5 in suitable places. The identifier max can now be used as a denotation, e.g.:

```
ROW max INT VAR weight ;
FOR t FROM 1 UPTO max
REP
  get ( weight [ t ] )
ENDREP
```

In this example, the elements of the weight are read successively with the operation get. As shown in this example, rows and for-loops work together nicely; the use of synonyms assures that the same range of index values is used.

Chapter 3

Examples Elan-0 subset

The following examples are intended to give a flavour of the Elan-0 subset and of the style of programming that can be achieved with it. Further examples (and much more advanced examples) can be found on the distribution disc.

3.1 Horse race

The following program performs a race with 6 horses. It was developed by pupils from a school in Hungary, under supervision of Peter Hanak. It could be extended with a mechanism to accept bets. The program makes use of the `cursor` function to organize the layout of the screen. It uses `choose128` to produce (quasi-)random numbers.

```
LET no of horses = 6 ;

program :
  start horses ;
  REP
    choose horse ;
    move horse
  UNTIL
    finished
  ENDREP ;
  display winner .

start horses :
  INT CONST start pos :: 12 ;
  INT CONST end pos :: 50 ;
  ROW no of horses INT VAR horse ;
  display title ;
  INT VAR i ;
  FOR i FROM 1 UPTO no of horses
  REP
    put horse at startpos ;
    mark start of track ;
    mark end of track
  ENDREP .

display title :
  cursor ( endpos DIV 2 , 1 ) ;
  put ( "H O R S E   R A C E" ) .
```

```
put horse at startpos :
  horse [ i ] := startpos .

choose horse :
  INT CONST ix :: ( choose128 MOD no of horses ) + 1 .

mark start of track :
  cursor ( 1 , 2 * i + 1 );
  put ( i ) ;
  put ( "*" ) .

mark end of track :
  cursor ( endpos , 2 * i + 1 ) ;
  put ( "|" ) .

move horse :
  cursor ( horse [ ix ] , 2 * ix + 1 ) ;
  put ( ".*" ) ;
  horse [ ix ] INCR 1 .

finished :
  horse [ ix ] >= endpos .

display winner :
  cursor ( start pos - 1 , 2 * no of horses + 4 ) ;
  put ( "The winner is horse number:" ) ;
  put ( ix ) ;
  line ( 2 ) .
```

3.2 Drawing a box

This example is a suitable demonstration for Top-Down programming. How does one draw a box on a conventional screen?

```
draw box :
  ask size ;
  draw lid ;
  draw sides ;
  draw bottom .

ask size :
  INT VAR size ;
  line ;
  put ( "size = " ) ;
  get ( size ) ;
  line ( 2 ) .

draw lid :
  put ( size * stripe ) ;
  line .

draw sides :
  INT VAR i ;
  FOR i FROM 1 UPTO size
  REP draw slice
  ENDREP .
```

```
draw bottom : draw lid .

stripe : "--" .

draw slice :
  put ( pip ) ;
  put ( ( size - 2 ) * blank ) ;
  put ( pip ) ;
  line .

pip : "!!" .

blank : " " .
```

3.3 Circular shifting

The operations on texts `HEAD` and `TAIL` that are available in Elan-0 differ markedly from the standard operations in the language, being much more list-oriented. In standard Elan they can be programmed as

```
TEXT OP HEAD ( TEXT CONST a ) :
  a SUB 1
ENDOP HEAD ;

TEXT OP TAIL ( TEXT CONST a ) :
  subtext ( 2 , LENGTH a , a )
ENDOP TAIL ;
```

The following program repeatedly rotates its input text by one position until the original is obtained again.

```
rotate :
  declare texts ;
  REP
    shift s circularly ;
    display s
  UNTIL
    s = original
  ENDREP .

declare texts :
  TEXT VAR original ;
  put ( "Text, please?" ) ;
  get (original ) ;
  TEXT VAR s :: original .

display s :
  line ;
  put ( s ) .

shift s circularly :
  s := ( TAIL s ) + ( HEAD s ) .
```

3.4 Converting numbers into texts

Designing a program for conversion between numbers and texts is a good way to get used to the respective properties of numbers and texts. The program illustrates the use of `CAT` and `SUB`.

```
outint :
  put ( "This program converts a positive integer" ) ;
  line ;
  put ( "to a given radix in range 1 to 16." ) ;
  line ;
  ask for radix ;
  WHILE
    another number ;
  REP
    represent number according to radix ;
    print representation
  ENDREP.

ask for radix :
  INT VAR radix ;
  put ( "Radix, please:" ) ;
  get ( radix ) ;
  line .

another number :
  ask for number ;
  number > 0 .

ask for number :
  INT VAR number ;
  put ( "number, please:" ) ;
  get ( number ) ;
  line .

represent number according to radix :
  TEXT VAR representation :: "" ;
  REP
    isolate a digit ;
    add this digit to the representation
  UNTIL
    no more digits
  ENDREP .

isolate a digit :
  INT CONST digit :: number MOD radix ;
  number := number DIV radix .

add this digit to the representation :
  representation := representation of digit + representation .

no more digits :
  number = 0 .

representation of digit :
   IF digit > 15
   THEN "?"
   ELSE "0123456789ABCDEF" SUB ( digit + 1 )
   FI .
```

```
print representation :
    put ( "Representation = " ) ;
    put ( representation ) ;
    line .
```

3.5 Guessing numbers

The following example is due to Leo Geurts (Centrum voor Wiskunde en Informatica, Amsterdam). By means of the halving algorithm it guesses a number chosen by the human opponent.

```
how to play :
  tell the rules ;
  all numbers 0 to 99 are possible ;
  REP
    make a guess ;
    wait for reply ;
    halve the range
  UNTIL
    good OR impossible
  ENDREP ;
  tell result .

tell the rules :
  put ( "Think of a number from 0 to 99." ) .

wait for reply :
  TEXT VAR reply ;
  get ( reply ) ;
  WHILE reply <> "y" AND reply <> "h" AND reply <> "l"
  REP
    line ;
    put ( "Possible answers are y(es), h(igh), l(ow)" ) ;
    get ( reply )
  ENDREP .

halve the range :
  IF reply = "l"
  THEN
    min := guess + 1
  ELIF reply = "h"
  THEN
    max := guess - 1
  FI .

good :
  reply = "y" .

impossible :
  min > max .

all numbers 0 to 99 are possible :
  INT VAR min :: 0 ;
  INT VAR max :: 99 .
```

```
make a guess :
  INT CONST guess :: ( min + max ) DIV 2 ;
  line ;
  put ( "Is it" ) ;
  put ( guess ) ;
  put ( "?" ) .

 tell result :
  line ;
  IF good
  THEN
    put ( "Good!" )
  ELSE
    put ( "Cheat!" )
  FI .
```

3.6 Guess my age

This example is also due to Leo Geurts. This time the player has to guess a randomly chosen "age" It is a good opportunity to learn, by experiment, the value of the halving algorithm.

```
how to guess :
  choose a number ;
  look for a customer ;
  let him guess ;
  WHILE not guessed
  REP
    give a hint ;
    another guess
  ENDREP ;
  applause .

choose a number :
  INT VAR number :: choose128 .

look for a customer :
  put ( "Guess my age " ) .

let him guess :
  INT VAR guess ;
  get ( guess ) .

not guessed :
  guess <> number .

give a hint :
  line ;
  IF guess > number
  THEN
    put ( "Too high, try again " )
  ELSE
    put ( "Too low, try again  " )
  FI .

another guess :
  get ( guess ) .
```

```
applause :
  line ;
  put ( "Correct!" ) ;
  line ( 3 ) .
```

Chapter 4

The Elan Programming Environment

The user interface of the Elan Programming Environment is by itself simple, but its description gets rather complicated because of the many ways of interaction with the user. For concise description, we will denote the "return" or "enter" key by `<RET>` and the "delete" or "rubout" key by `<DEL>`, the "backspace" key by `<DEL LEFT>`. The `<BREAK>` is a special key to notify the Elan Programming Environment to stop whatever it is doing. Its realization may well be different for the various implementations (usually CNTL-C, BREAK-key, special buttons, etc.; read the documentation which is distributed on the floppy disk with the software). In showing screen output, the cursor will be depicted as □.

return key
delete key
backspace key
break key

4.1 Components of the Elan Programming Environment

The Elan Programming Environment conceptually consists of six functional modules, communicating by way of a common data structure (the *memory*) and invoking (in some cases recursively) each other's services.

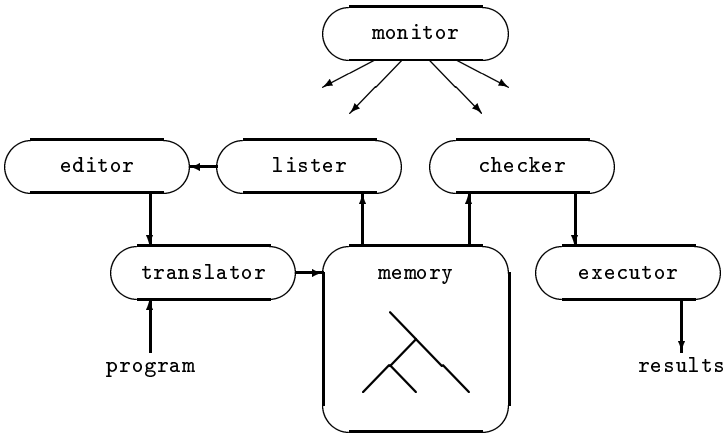
memory

4.1.1 Modules of the Elan Programming Environment

The modules of the Elan Programming Environment are:

- The *monitor*, acting as a command interpreter, provides most of the user interface and invokes all other modules. — monitor
- The *translator* accepts input of definitions, translates them to internal form and stores them into memory. — translator
- The *lister* provides a structured overview of the defined names and their definitions. — lister
- The *editor* takes care of all text input, for example when entering or editing a definition. — editor
- The *checker* performs the checking of some static properties of the program prior to its execution. — checker
- The *executor* executes checked programs. — executor

The relationship between these modules is displayed in the following figure:



4.1.2 The memory

memory

The *memory* holds the following information:

name list
- a table of all names with their attributes (the *name list*),

stack
heap
- the *stack*, the *heap* and

program
- the definitions forming the *program*, in some internal form.

Unfortunately, present-day computers do not retain the contents of their memory upon being switched off, so that the memory must be explicitly written to a file in order to be able to read it back later.

recycling

During execution the executor tries to *recycle* all space in the heap taken up by objects that are no longer needed. It may however happen that a program needs more space than is available. Thus the memory can get exhausted; the only way out is to save the program in a file (by means of a write-command) and to start again.

4.1.3 File store

file system

The Elan Programming Environment was designed to run under any operating system on a variety of compilers. It uses the *file system* of the host computer for storing files, adhering to the conventions of that system.

4.2 The user interface

4.2.1 Moods

moods

From the standpoint of the user, the Elan Programming Environment can be in a number of *moods* (states), each with its own behaviour. In each of those moods, the Elan Programming Environment accepts a number of single-letter commands. These moods, with their associated commands are:

- command-mood
  `c d e f g i l n o p q r s t u v w x z` (see 4.3)
- edit-mood
  `<RET> <BREAK>` (see 4.4)
- execute-mood
  `<BREAK>` (see 4.5)

- backtrace-mood
  `e n q s` (see 4.5.2)
- trace-mood
  `b n p x c e q s <BREAK>` (see 4.5.3)
- verify-mood
  `b n p x c e q s <BREAK>` (see 4.5.4)

The current mood is indicated by a message in the right-hand corner of the bottom line of the screen, the *status line*. The left-hand corner of the status line is used for error messages. status line

Each mood has its own set of possible commands, some of which will cause the Elan Programming Environment to switch into another mood.

4.2.2 Commands

Commands consist of single letters. On some computers they may be realized as special function keys or as choices from a menu. Commands are not echoed on the screen, and are obeyed immediately, without waiting for a `<RET>` key to be pressed. This contributes to the interactive feeling of the Elan Programming Environment. command

To an unknown or unacceptable command the Elan Programming Environment reacts by showing on the status line a *menu* of all acceptable commands (we use the *negative menu* technique: a menu is displayed only when an unacceptable command is given). In all moods except edit-mood and execute-mood the letter `h` (help-command) can be used to provoke such a menu. menu

4.2.3 Names

The Elan Programming Environment knows at any time a collection of names, each of which may be *undefined*, or have one or more definitions. Under the guidance and control of the Elan Programming Environment names can be manipulated and definitions supplied to form a program. All names which are known to the Elan Programming Environment are stored in the *name list*. name list

A name with which one or more definitions have been associated we will call a *defined* name. Depending on the way in which their definitions are brought into the Elan Programming Environment these are either *visible* or *hidden*. Definitions from packets (for example the standard library) are hidden, the others are visible. In an overview of known names the Elan Programming Environment will show only those names which have associated a visible definition. visible definition, hidden definition

Names which do not have any associated definition are called *undefined*. Once a name is mentioned to the Elan Programming Environment it will remain in the name list even when it is undefined. It is important to know this when using abbreviated names (see later).

Some names, as for example the keywords of Elan, look like valid names, but no definition can be associated with them. These are called *undefinable*.

4.2.4 Focus and prompt

There is always one name, called the *focus*, which is the current center of interest. After the completion of each command, the Elan Programming Environment prompts with the focus, indicating its readiness to accept further commands. The focus is extended by a type indication, indicating whether there exists a definition associated with the name, and if so, what kind of definition (refinement, `PROC`edure, `OP`erator, `LET`, `TYPE` or `PACKET`). focus, prompt

Undefined names are recognized by a question mark:

```
program ?
```

or

```
RESL ?
```

Refinement names have a colon mark:

```
take next:
```

generic name

The names of procedures and operators are *generic*, i.e. they can have more than one definition. The headings of all definitions of the name are shown. Procedures and operators are indicated like:

```
FROM PACKET standard library
  PROC put (FILE CONST f, TEXT CONST t)
  PROC put (FILE CONST f, REAL CONST r)
  PROC put (FILE CONST f, INT CONST i)
  PROC put (TEXT CONST a)
  PROC put (REAL CONST a)
  PROC put (INT CONST a)
```

or

```
FROM PACKET standard library
  OP CAT (TEXT VAR a, TEXT CONST b)
```

`LET` definitions for values and types have a let mark:

```
LET n
```

or

```
LET VECTOR
```

`TYPE` definitions are displayed like:

```
TYPE T
```

Initially, the focus is the name `program`, being as yet undefined. Thus, the initial prompt looks like:

```
program ?
```

Another name can be chosen as focus by the focus-command (see 4.3). Upon focussing on a generic name the cursor appears at the heading of the first definition. By (repeatedly) giving a next-command (`n`) or up-command (`u`), it is possible to navigate over the various definitions of a generic algorithms, e.g. (after one `n`):

```
FROM PACKET standard library
  PROC put (FILE CONST f, TEXT CONST t)
  PROC put (FILE CONST f, REAL CONST r)
  PROC put (FILE CONST f, INT CONST i)
  PROC put (TEXT CONST a)
  PROC put (REAL CONST a)
  PROC put (INT CONST a)
```

It is now the second definition which is the focus for e.g. an edit-, delete- or show-command.

4.2.5 Program and root

root

To the Elan Programming Environment, a program does not consist of one sequential text but rather of a collection of independent definitions, whose order plays no role. In order to construct a program, its definitions have to be input one by one. Some commands (the check-command and the execute-command) require the focus to be a refinement, taken as the entry point of the program. This refinement is called the *root* of the program. By default the Elan Programming Environment assumes the first refinement entered or read from a file to be the root of the program. Apart from inspecting and modifying the program under devellopment, it is also possible to inspect the underlying *packets* which each form a seperate scope, similar to the main packets scope. To enter a packet scope, focus on the packet name an issue the into-command. Now you can list and inspect all definitions in this packet. To return to te main packet scope, issue the out-command.

packets

4.2.6 Initial state

initial state

In the *initial state* the Elan Programming Environment is in command-mood and its memory contains only the definitions of the standard library. On the screen can be seen an identification of the Elan Programming Environment. The initial prompt indicates that the focus is `program`, as yet undefined, which serves as a suitable root for many programs.

4.3 The command-mood

command-mood

The *command-mood* can be recognized by the message `Command, please...` on the right-hand side of the status line. In command-mood, the commands listed below are accepted. Most of them have the focus as an implicit parameter. After the execution of each command the Elan Programming Environment prompts with the current focus and returns to the command-mood.

- `f` *focus-command*

  focus-command

  The focus-command shows `Focussing...` on the status line, and asks for the name which should become the focus of interest. The focus-command serves to focus on a new name, thus allowing navigation over program parts.

  abbreviated name

  The focus-command allows a defined name to be abbreviated by replacing its last characters by a star (e.g. `prog*`). The Elan Programming Environment then searches the name list for a match, and complains `Known name ?` if no match is found.

- `e` *edit-command*

  edit-command

  The edit-command serves to assign a new definition to the focus, or to modify the definition of the focus.

  The name and (if present) the body of the definition whose name is the focus are shown on the screen and an opportunity is given for local editing. On the status line `Input, please...` is displayed (see 4.4.1 for a description of the edit-mood).

- `s` *show-command*

  show-command

  The definition of the focus is shown on the screen. In case the focus is a generic name, with multiple definitions, the definition indicated by the cursor is shown (the cursor can be moved to another definition of the focus by the next-command `n`) or the up-command `u`. Immediately after the execution of a program it is also possible to focus on an object created during the execution; in that case its type, access attribute, name and value can be inspected by the show-command. Any edit- or read-command hides the results of the previous execution.

next-command

- `n` *next-command*

  The next-command serves to move the cursor over the various definitions of a generic name. It has no effect for non-generic names.

up-command

- `u` *up-command*

  This command serves the same purpose as the next-command, but works in the opposite direction.

execute-command

- `x` *execute-command*

  The execute-command serves to execute the program whose root is the focus. It shows `Executing...` on the status line. After execution of a program, its objects (variables and constants) can be inspected by means of the show-command. At the start of an execution, all objects are made undefined. See section 4.5 for a description of the execute-mood.

generate-command

- `g` *generate-command*

  The generate command (which is available in Version 2.0 and higher of the Elan Programming Environment) serves to compile the program whose root is the focus to (relatively fast) executable code. It asks for the name of a file, to which the code is to be written. If a file with that name exists, it is overwritten. The program has to be loaded and executed outside the Programming Environment.

trace-command

- `t` *trace-command*

  Same as the execute-command, but the execution takes place in trace-mood. It shows `Trace command, please...` on the status line. See section 4.5.3 for a further description of the trace-mood.

verify-command

- `v` *verify-command*

  Special form of tracing execute-command, in which the types of the syntactical constructs are shown rather than their values. This mode is recognized by the request `Verify command, please...` on the status line. See section 4.5.4 for a further description of the verify-mood.

list-command

- `l` *list-command*

  The list-command serves to give a overview of all names in the cuurent scope (usually the main packet scope) having a visible definition. This overview begins with a bottom-up part:

  view

  - the names of the packets which have been read,
  - the names of abstract types,
  - the synonyms and
  - the names of procedures and operators.

  After this a structured overview of the refinements of the program is given. If the focus is a refinement, the names of all refinements which appear in its body are displayed with a suitable indentation on the next line(s). The process is invoked recursively if a refinement is expressed in terms of other refinements, with the exception that no name appears more than once in the overview.

  After this, a list is given of all refinements which remain, and so are no part of the program having the focus as root. Some of them might be candidates for deletion.

  Names from the standard library and from a packet are not listed. It is however possible to focus on such a name and show its definition.

delete-command

- `d` *delete-command*

  The delete-command deletes the definitions of the current focus.

  The Elan Programming Environment asks for confirmation (to be answered with `y` or `n`) before doing anything so drastic. Definitions in packets cannot be deleted.

- `r` *read-command* read-command

  The read-command serves to read a program, which was previously written to a file, back into memory. It reports `Reading...` on the status line. It adds the definitions of that program to the current contents of the memory, overwriting refinements with the same name. It may be necessary to first save the current program by writing it to a file (`w`), or to first clear the memory (`c`).

  The read-command asks for the name of a file. If a file with that name is present, the program it contains is read. After reading, the name of its first refinement (or `program` in case there is no refinement) will be the new focus. During the reading of the program, the names of the definitions are listed on the display. Finally a view is given of all definitions. If, however, a packet is read with this read-command the packet interface is ignored and all definitions in the file are added to to the main program.

  If a file with the desired name was not present, the Elan Programming Environment produces an overview of all program files that are present (again a negative menu).

  The conventions for file names are those of the operating system running the Elan Programming Environment. file name

- `p` *packet-command* packet-command

  The packet-command serves to read a packet into memory. It reports `Reading...` on the status line. It is a variant of the read-command, with the following differences:

  - When reading a program, this packet-command acts as if a read-command was issued.
  - When reading a packet, definitions read by the packet-command are hidden inside the packet scope: they are not mentioned by the list-command. The exported definitions can be inspected by the show-command. However, they can not be modified by an edit-command.

- `w` *write-command* write-command

  The write-command serves to write all definitions in the current scope (definitions shown by the list-command) from memory onto a file, starting with the current focus. If the current scope is inside a packet the interface is writen as well. It reports `Writing...` on the status line. It asks the user for a file name. Any existing file of that name is overwritten.

  The conventions for file names are those of the operating system running the Elan Programming Environment.

- `z` *write-packet-command* write-packet-command

  The write-packet-command has the same effect as the write-command, apart from the fact that it writes the visible definitions from memory in the form of a packet. It asks for the name of the packet to be written, which is also the filename (appended with some suffix). It then constructs an interface in interaction with the user, by showing in turn all exportable names and giving the user an opportunity to indicate his desires:

  - `n` no, don't export this name;
  - `y` yes, export it;
  - `s` show the definition(s) of the current name; or

– `q` quit, do not write this packet.

Finally, if there are any visible refinements, it asks for the name of the root (`prelude:`) of the packet. Only after all this interaction, the packet is written.

into-command

- `i` *into-command*

  After focussing on a packet name, we can step into that packet by issuing the into-command. Now it's possible to focus on all the definition in this packet and inspect them.

out-command

- `o` *out-command*

  After stepping into a packet you want to return to your main program. This can be done by typing the out-command (`o`).

clear-command

- `c` *clear-command*

  The clear-command, upon confirmation, clears the memory, bringing the Elan Programming Environment back into its initial state. It reports `Clearing...` on the status line.

quit-command

- `q` *quit-command*

  The quit-command, upon confirmation, halts the Elan Programming Environment and returns control to the operating system of the computer.

4.4 Reading and editing of programs

While reading or editing a program, the Elan Programming Environment accepts text from a file or from the keyboard, one definition at a time, and translates it to internal form, performing a running Context-Free syntax check as the lines come in.

incremental syntax check

Upon finding a syntactic error, the translator attempts to arrive at a syntactically correct program in interaction with the user, offering the incorrect definition for local editing as often as necessary. By hitting `<BREAK>` the user may end this attempt.

replay

The editing of existing parts of a program is based on *replay*: some definition is displayed on the screen, and can be modified at will by the user, after which the translator reads the text on the screen as input. The new definition may overwrite the old one. Once a line has been read, it can no longer be edited (the cursor refuses to go up) but whenever a syntax error is found, also the lines preceding it can be edited.

4.4.1 Local editing

edit-mood

Local editing is performed in *edit-mood*, which is recognized by `Input, please...` on the status line. Local editing allows the user to enter and modify a text field (which may well be longer than a line on the screen). Local editing is ended by hitting `<RET>` (or aborted by hitting `<BREAK>`). Up to this event, the text field can be modified by modifying its image on the screen.

During local editing, the cursor can be moved freely over the screen within specific boundaries. Assume zero or more lines have been entered and the cursor is somewhere within this field.

- By means of `<RET>` the user indicates that this line of input is completed; the translator now starts processing it. After processing a complete definition the translator returns to command-mood, otherwise it recursively asks the editor for a next line of input.
- With the `<BREAK>` key the text modification or entering can be aborted in such a way that it has no effect.

- The <DEL> key deletes the character under the cursor, if any.
- The <DEL LEFT> key deletes the character to the left of the cursor, if any.
- The arrow keys allow the movement of the cursor over the text field (but not outside it).
- Any key which is not a control key inserts the corresponding character at the position of the cursor, and moves the cursor right.

4.4.2 Incremental correction

Whenever the translator finds a *syntax error*, i.e. it is of the opinion that a specific symbol was omitted or if it expects a specific syntactic construction (identifier; attribute VAR or CONST; unit or declaration ...) it gives an error message to that effect in the lower left corner of the screen and offers the directly surrounding definition for local editing. The cursor is positioned at the place of the supposed error. As an example, suppose the user types as a unit syntax error

```
ROW INT VOR a
```

The translator complains Number of elements ? and offers

```
ROW INT VOR a
```

The user dutifully inserts 10 and hits the return key. The translator now complains VAR/CONST ? and offers

```
ROW 10 INT VOR a
```

The user changes VOR into VAR and hits the return key <RET>, whereupon the translator accepts the rest of the line in silence and waits for the next line. This same incremental correction facility is available for correcting input during reading from a file.

As the Elan Programming Environments does not impose restrictions on the order of the definitions and the user might introduce all kinds of weird operators, like THAN, situations can occur in which the error signalling is not so helpful. For example, if the user types

```
IF a>=0 THAN a ELSE -a FI
```

the Elan Programming Environment will now complain THEN ? and offer

```
IF a>=0 THAN a ELSE -a FI
```

apparently considering THAN to be meant as an operator and so interpreting this construction as

```
IF a >= (0 THAN a) ELSE -a FI
```

The error reported on the bottom line of the screen should be seen as just a suggestion! It is the best the programming environment can do, but it is up to the user to decide what it was he wanted to express and how to repair the error.

4.4.3 Alternative representations

In Elan, a number of symbols possess more than one representation:

```
REP          REPEAT
ENDREP       ENDREPEAT      END REP
FI           ENDIF          END IF
ENDPROC      END PROC
ENDOP        END OP
```

The same holds for comment brackets (see 5.5.4).

On displaying or saving a program, the Elan Programming Environment prefers the representations in the left column of the table.

4.4.4 Break

If the user hits `<BREAK>` during input, the translator is aborted and the Elan Programming Environment reverts to command-mood. This facility is helpful in order to recover from a total tangle of errors during input from a file.

4.5 The execute- and related moods

executor
execute-mood

The *executor* calls the checker and, if no errors were found, starts executing the program. Usually, it immediately starts the program which has the current focus as its top-level refinement. If, however, some of the currently loaded packets contain a root (prelude), these are executed first. If an error occurs, a back-trace is given (see 4.5.2).

Execution can be terminated by giving a `<BREAK>`, upon which the Elan Programming Environment reverts to trace-mood.

4.5.1 The checker

checker

The *checker* is invoked automatically before execution. It takes at most a few seconds, showing `Checking...` on the status line. It checks, amongst others, the following:

- is every applied name defined exactly once?
- do types match in
  - source and destination of an assignation?
  - all parts of a conditional?
  - a numerical choice?
- are all operations defined for the type of operands given?
- are all conditions of type `BOOL`?
- are all indices and bounds of type `INT`?
- are all identifiers, used as bounds, synonym identifiers?
- are only rows subscripted?
- are only fields selected from?

Furthermore, it performs the identification of generic algorithms, reporting errors by giving a backtrace.

4.5.2 The backtrace-mood

semantic error
backtrace-mood

Whenever the Elan Programming Environment finds a *semantic error*, it enters the *backtrace-mood*, displaying `Backtrace command, please...` on the right of the status line, with an error description on the left of the status line. The backtrace-mood offers to the user the opportunity of unfolding the static nesting of the present unit and listing it. After each unit listed, the Elan Programming Environment waits for the next wish of the user, which can be one of the following:

- `e` edit-command

  modify the visible definition containing this unit and return to the command-mood.

- `n` next-command

  continue backtracing; return to the command-mood if the current unit is the root of the program, otherwise display the unit immediately surrounding the current unit.

- `s` show-command

  show the definition and the value of a name, which is asked from the user. This gives an opportunity to inspect local variables, parameters etc.

- `q` quit-command

  stop backtracing, return to command-mood.

This mechanism serves to pinpoint semantic errors in the program.

4.5.3 The trace-mood

The *trace-mood* can be entered by the user by means of a trace-command (`t`). It can also be entered from a program by a call of `assert`. In the trace-mood, which is indicated by `Trace command, please...` on the status line, the executor lists every unit before executing it, and asks for a command as follows: trace-mood

- If the unit is simple (i.e. not a invocation of a procedure, refinement or operator and not a control structure), it is executed. If this unit yields a result, this is displayed.
- If the unit is such an invocation or a control structure, it is listed and the executor waits for one of the following commands:
  - `b` backtrace-command

    The Elan Programming Environment switches to the backtrace-mood.
  - `c` continue-command

    The remainder of the program is executed without trace.
  - `e` edit-command

    Execution is terminated, and the definition that contains the current unit is offered for local editing.
  - `n` next-command

    The body of the current unit is executed in trace mode.
  - `p` previous-command

    All the remaining units at the present level (entered by the last next-command) are executed (without trace), if the body yields a result this is displayed and the trace-mood is re-entered.
  - `q` quit-command

    Return to the command-mode.

- `s` show-command
  A known name (may be abbreviated) is asked and the definition and the definition of that name is displayed.
- `x` execute-command
  The body is executed (without trace), its result (if any) is displayed and trace-mood is re-entered.

At the end of each body the executor waits again for a valid trace-command.

4.5.4 The verify-mood

verify-mood

In some cases deeper insight in the cause of a semantic error may be acquired from stepwise inspection of types of program constructs. This can be accomplished by the verify-command, which causes the checker to run in trace-mood. Its behaviour is analogous to the trace-command, with the exception that the types of the program constructs are displayed rather than their values.

Chapter 5

An overview of Elan

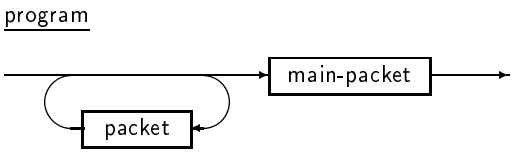
In this overview of Elan as implemented in the Elan Programming Environment, we paraphrase the syntax of the language , introducing terminology for the most important constituents of a program and discussing the semantics of the various constructs. The more noticeable differences with standard Elan and its Eumel variant are indicated.

We assume the reader to be familiar with the notation of syntax-diagrams. For didactic reasons, there will be a large number of relatively simple syntax-diagrams rather than a small number of complicated ones. We use those diagrams not only for describing structure but also for introducing useful terminology.

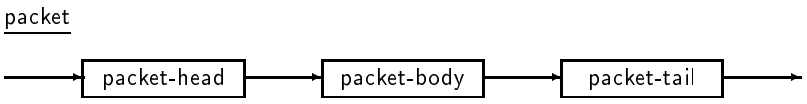
In this appendix the names of syntactic constructs will be written in sans serif font, using some spelling variations (like primaries rather than primarys) for linguistic reasons.

5.1 Programs and packets

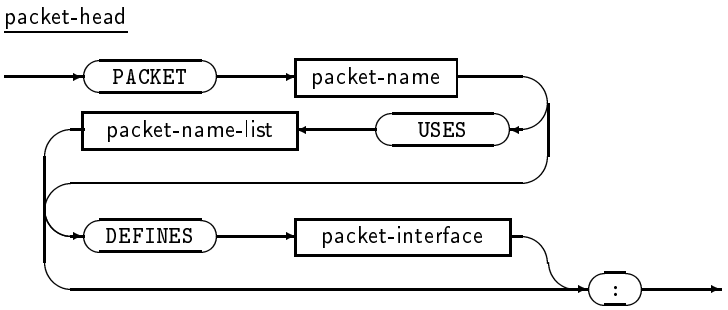
A program consists of zero or more packets followed by the main-packet.



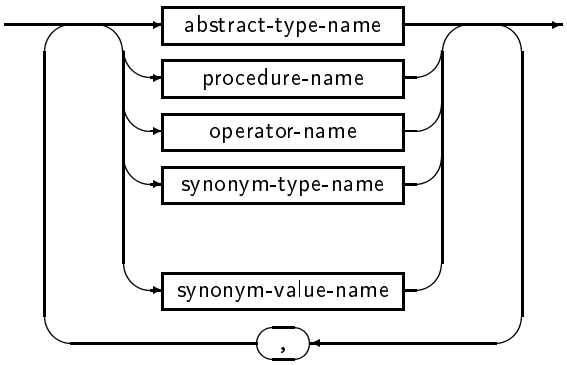
The execution of a program consists of the execution of its packets in textual order, followed by that of its main-packet. A packet has a head, a body and a tail.



A packet is executed by executing its packet-body.



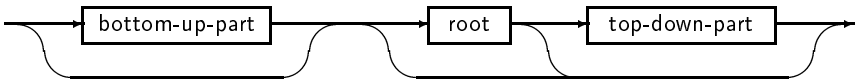
packet-interface



The packet-interface lists the names of all entities (objects, types and algorithms) exported by
export the packet. An exported entity is made visible in all subsequent packets which do not define an entity with which it is incompatible. Refinements and variables can not be exported.

The syntax of the packet-body is somewhat simplified with respect to the standard language.

packet-body

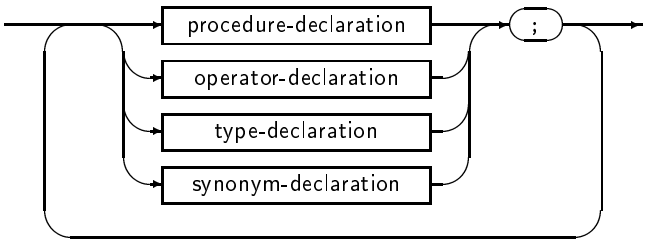


The execution of a packet-body is the execution of its bottom-up-part followed by the execution of its root, which may in its turn involve the execution of some refinements in the top-down-part.

root

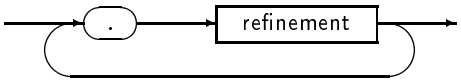
The root of the main-packet is either (as in standard Elan) a paragraph or a refinement. If the root of the program is a paragraph, it is treated by the Elan Programming Environment as an unnamed refinement, which obtains the name `program`.

bottom-up-part



The bottom-up-part comprises those declarations which precede the root and can be considered as a language fundament on which the rest of the program is to be built. It is executed by executing those declarations.

top-down-part

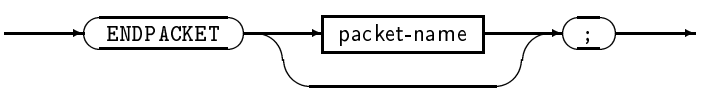


The top-down-part comprises the refinements that can be invoked from the root. The refinements in the top-down-part can not be invoked from a declaration in the bottom-up-part.

The Elan Programming Environment accepts as input any sequence of declarations, other units and refinements and distributes those elements over the three components of the main-
layout packet in their order of arrival. Therefore the *layout* and order of input to the Elan Pro-

gramming Environment can be in a very relaxed style. In outputting the program the Elan Programming Environment imparts its own strict layout conventions and structure to the program.

packet-tail



In the packet-tail, the name of the packet may appear a second time, in order to allow a check for "runaway" packets.

main-packet

The main-packet is a packet stripped of its head and tail. In the Elan Programming Environment, a packet can be developed by interactively constructing a main-packet and then encapsulating it into a packet.

5.2 Declarations

A *declaration* is a construct that, upon execution, binds a name to a value (object-declaration, synonym-declaration), to a declarer (type-declaration, synonym-declaration) or to a piece of program (procedure-declaration, operator-declaration, refinement). declaration

Apart from this dynamic effect a declaration has a static effect: Its occurrence makes the name, defined by it, visible in a specific part of the program, the *scope* of the declaration, together with the type and access-attribute with which it is defined. scope

The scope of a declaration occurring within a procedure (operator) declaration is that procedure (operator) declaration. The same holds for its parameters. The scope of a declaration occurring within a packet is that packet plus any packets to which it is exported.

In extension to the standard language, we allow procedures, operators and types to be *polymorphic*, i.e. to be equipped with type parameters. polymorphic

5.2.1 Bottom-Up declarations

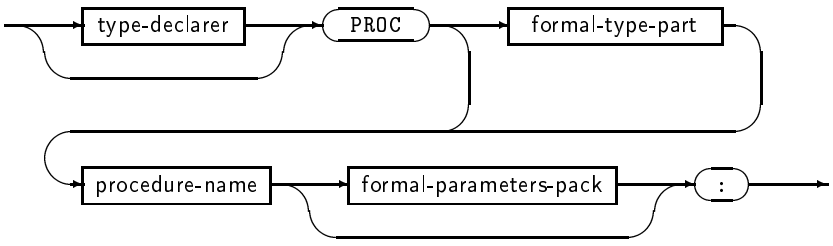
We will first describe those declarations that occur in the bottom-up-part of a program.

5.2.1.1 Procedure-declarations

A procedure has a head, a body and a tail.

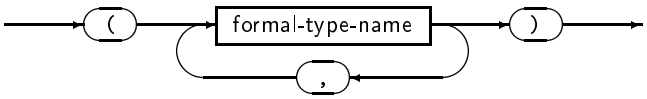
procedure-declaration

procedure-head

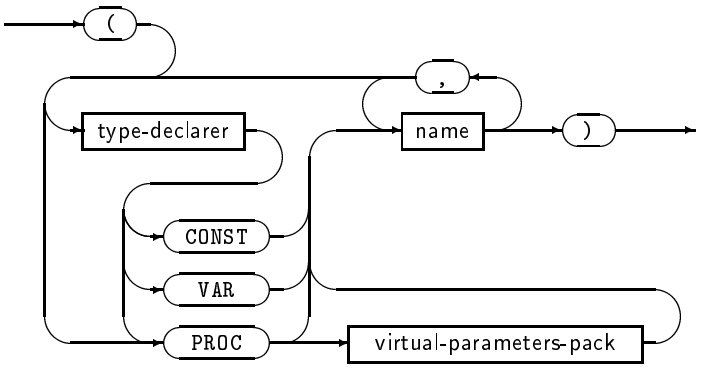


The procedure-head gives the procedure-name, the types and access-attributes of its parameters (if any) and the type of its result (if any). For polymorphic procedures, the formal-type-part lists the formal-type-names that occur in the procedure-declaration.

formal-type-part



formal-parameters-pack

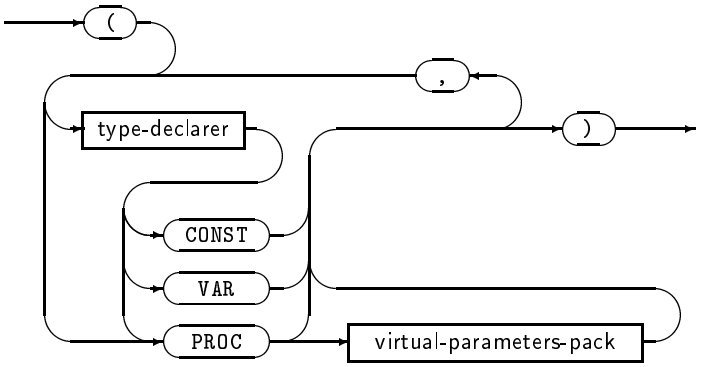


Parameters are either objects or procedures, as can be deduced from this rather unwieldy syntax diagram. In case a procedure is to be passed as a parameter, the types of its parameters are in their turn to be specified precisely by means of a virtual-parameters-pack.

parameter passing

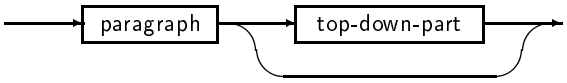
Parameters with CONST-access are passed by value, parameters with VAR-access are passed by alias.

virtual-parameters-pack



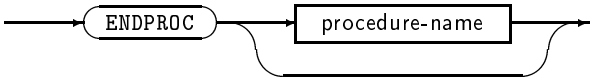
A procedure-body has the same form as a main-packet without a bottom-up-part.

procedure-body



The type of the procedure-body must be the same as the type of the result as given by the procedure-head.

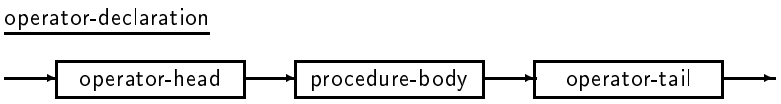
procedure-tail



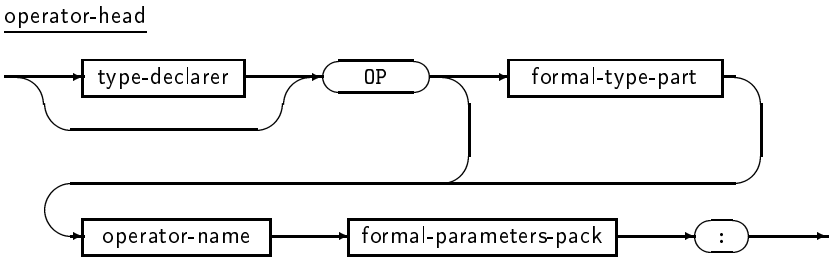
The name of the procedure is repeated after the ENDPROC symbol. In the Elan Programming Environment this name may be left out (in which case it is inserted automatically).

5.2.1.2 Operator-declarations

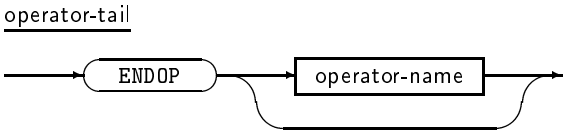
An operator-declaration follows the pattern of a procedure-declaration.



Only its head and tail are somewhat different.



An operator-head must contain either one (for monadic-operators) or two (for dyadic-operators) parameters. Again, for polymorphic operators the formal-type-part lists the formal-type-names that occur in the operator-declaration.



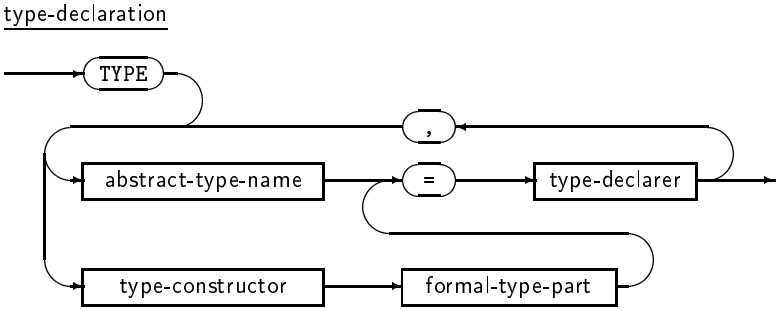
5.2.1.3 Type-declarations

A type-declaration gives an abstract-type-name to a type-declarer, the type of its *realization*. In the packet in which the abstract type is defined, the concretizer `CONCR` may be used to convert an object of that type to the type of the realization. In that packet, selection and subscription also have access to the realization of the type. Outside its defining packet, an abstract type is elementary and there is no direct way to access its realization (but this may be achieved indirectly, by the use of *access-algorithm*s defined in the same packet as the type).

realization

access-algorithm

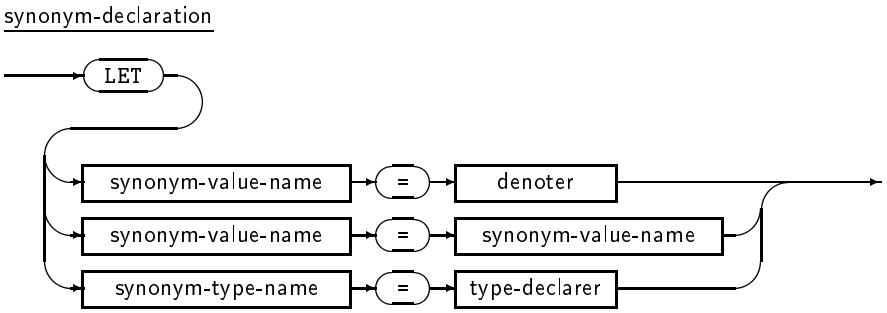
Because of these stringent restrictions on the visibility of the realization, type-declarations are much more typical for Bottom-Up and modular programming than the synonym-declarations.



In extension to standard Elan, a type-declaration may be polymorphic. In that case it defines a type-constructor, an abstract type parametrized with one or more formal types.

5.2.1.4 Synonym-declarations

A synonym-declaration binds either a name to a denoter (making that name synonymous with that denoter) or a bold-name to a type-declarer (making that bold-name synonymous to that type-declarer).



synonym

The *synonym* has all the properties of the denoter or type-declarer it is bound to - it may be used at all places where that would be valid, with the same meaning.

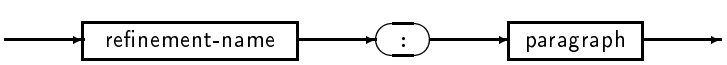
5.2.2 Top-Down declarations

Apart from the Bottom-Up declarations already described, Elan has Top-Down declarations for declaring objects and refinements.

Synonym-declarations may also be used as Top-Down declarations. In the Elan Programming Environment however, a synonym for a type-declarer may only be given in the bottom-up-part.

5.2.2.1 Refinements

Refinements serve to define algorithms in a Top-Down fashion.



A refinement gives a name to a paragraph. It is invoked by its name. The result (effect and value) of a refinement invocation is that of its paragraph.

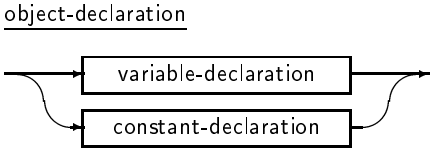
5.2.2.2 Object declarations

object

An object-declaration serves to define an *object*.

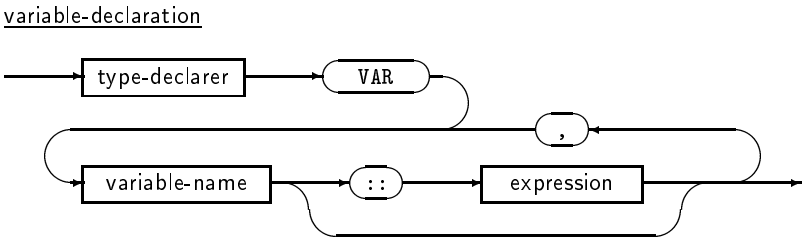
type
access-attribute
value

An object has a name, a *type*, an *access-attribute* (`VAR` or `CONST`) and (during execution) a *value*, which may be undefined. There are two forms of object-declaration:



variable

A variable-declaration declares one or more objects of one same type, with the access-attribute `VAR` (*variable*s).



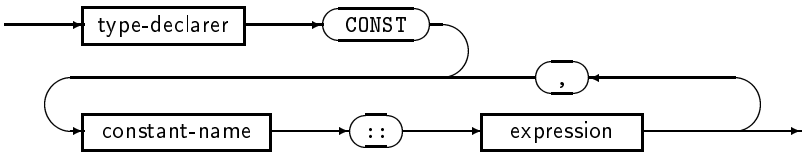
initialization

The expression preceded by the curious sign `::` is the *initialization* for the variable. Its value (or, if there is no initialization, an undefined value) is assigned to the variable-name.

constant

A *constant* is an object with the access-attribute `CONST` and always obtains a well defined value from its initialization.

constant-declaration



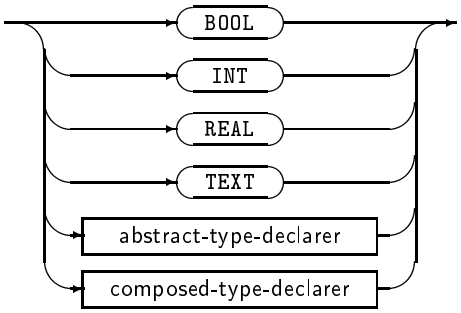
A variable can obtain another value by an assignation, whereas a constant cannot be assigned to.

If so desired, the access-attribute CONST may be left out, but this is not advised since it leads to degradation of syntactic error-detection. An object-declaration may very well occur in a repetition. Each time the declaration is executed, its initialization is executed anew.

5.3 Declarers and the type-system

Elan has a type system based on four concrete elementary types and two mechanisms for composing types, and gives to its users the opportunity to add further (abstract) types.

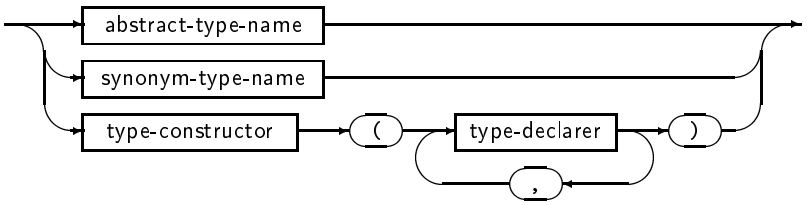
type-declarer



5.3.1 Abstract and polymorphic types

An abstract type can be introduced either by a synonym-declaration, in which case the synonym-type-name is merely a synonym for the type-declarer in its definition, or by a type-declaration, in which case it is to be distinguished from the type-declarer in its definition. In both cases it is represented by a bold-name.

abstract-type-declarer

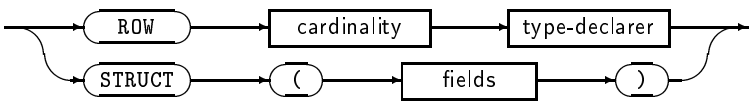


A type-constructor is explicitly parametrized with one or more types (in the form of type-declarers).

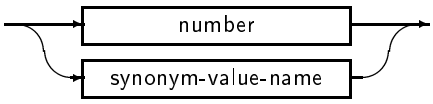
5.3.2 Composed types

There two types of composed values in Elan, rows and structures.

composed-type-declarer

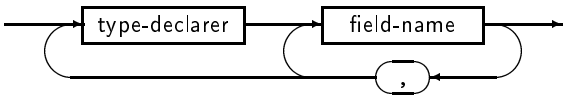


cardinality



The elements of a row all have the same type, and are numbered from 1 up to the cardinality of the declarer, which must be either a number or a synonym for a number. This cardinality is therefore fixed, it can not be the value of an expression other than a number.

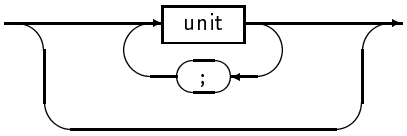
fields



The fields of a structure may have different types, and each field is tagged by a (different) field-name.

5.4 Paragraphs and their constituents

paragraph



The effect of the execution of a paragraph is the effect of the sequential execution of its units in textual order. The value (if any) of a paragraph is the value of its last unit. Notice that a paragraph may be empty. In that case it has neither an effect nor a value.

Within a paragraph, Elan allows a free mixture of Top-Down declarations and units.

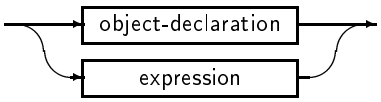
5.4.1 Units

yield
effect
result
action

A unit is a construct that, upon execution, may *yield* a value and have an *effect* (i.e. a change in the state of variables, input and output). Collectively, the value yielded and the effect are termed the *result* of the unit. Unless otherwise stated, the type of a unit is the type of the value yielded. A unit that yields no value is called an *action* and has the hypothetical type `VOID`.

All Declarations are actions.

unit

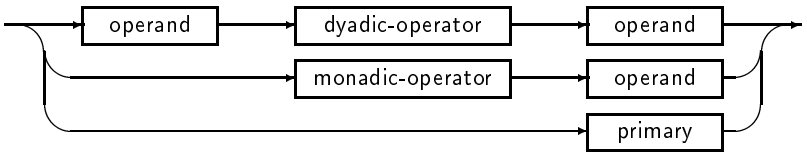


An expression is either a primary (in which case its result is that of the primary) or it is composed by operators out of smaller constructs. Its operands must then agree in number and type with the formal parameters of one of the definitions of its operator.

collateral

The expression is evaluated as follows: first its operands are evaluated *collateral*ly (i.e. in an unspecified order); then its result is that of the body of that definition, after binding its formal parameters to the corresponding operands of the expression. In case of a polymorphic operator, its formal-type-names are implicitly bound (as synonyms) to the types of its operands.

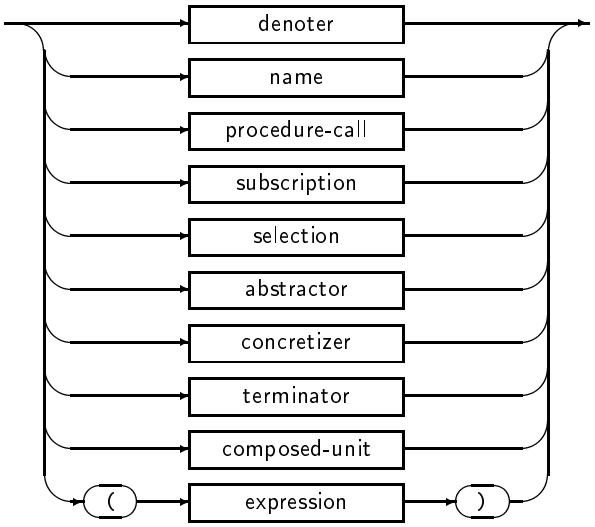
expression, operand



The syntax-diagram for expressions is ambiguous, and must be disambiguated by taking into account the priorities of the operators, which are as follows:

1	`:=`, `INCR`, `DECR`, `CAT`
2	all abstract dyadic operators
3	`OR`, `XOR`
4	`AND`
5	`=`, `<>`
6	`<=`, `<`, `>=`, `>`
7	`+`, `-`
8	`*`, `/`, `DIV`, `MOD`
9	`**`
10	all monadic operators

primary

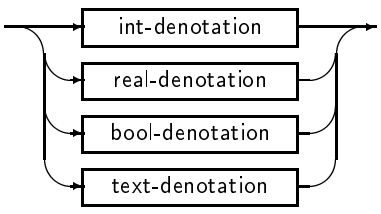


These constructs are explained in the following sections.

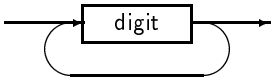
5.4.2 Denoters

Denoters serve to denote a value of a concrete type.

denoter

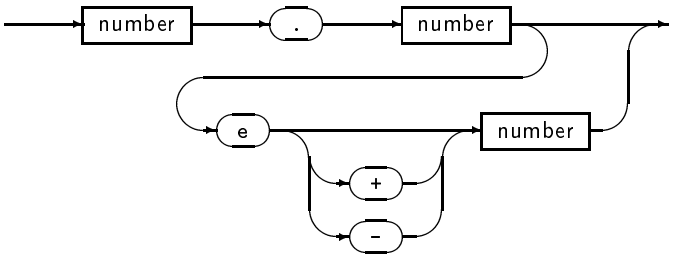


int-denotation, number

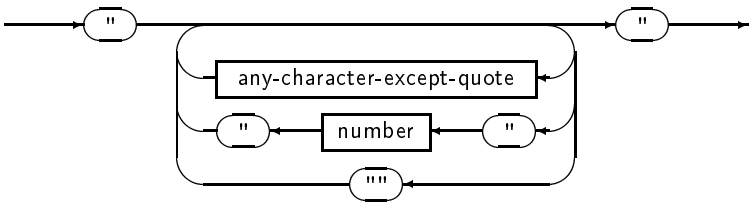


Notice that the int-denotation denotes an unsigned number, which must be preceded by a monadic minus to obtain a negative number.

real-denotation

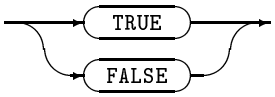


text-denotation



A text-denotation denotes the sequence of characters, obtained by stripping off its outermost quotes. Most characters, including the space, stand for themselves, but the quote-character is used as an escape. A number between quotes serves to denote the character whose code is the value of that number.

bool-denotation

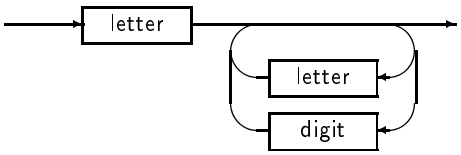


5.4.3 Names

identifier

Many names have the form of an *identifier*, a small (lower case) letter, possibly followed by some further small letters or digits.

name, packet-name, procedure-name, refinement-name
field-name, constant-name, variable-name, synonym-value-name

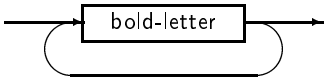


layout

Within a name, spaces may be used freely to enhance readability. Spaces are redundant and do not form part of the name, but the Elan Programming Environment conserves the spacing in an identifier at its first occurrence.

Types and operators have bold-names, written in capital letters.

bold-name, abstract-type-name, synonym-type-name
formal-type-name, type-constructor

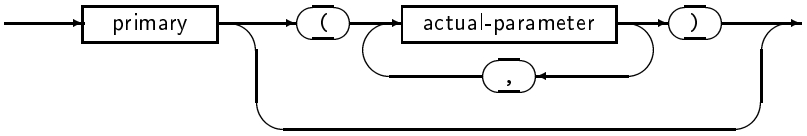


Spaces are not allowed in a bold-name. A number of operators have special symbols as names, such as + etc. These are listed in 5.4.1.

5.4.4 Calls

The call of a procedure with parameters is written in the usual prefix style.

procedure-call

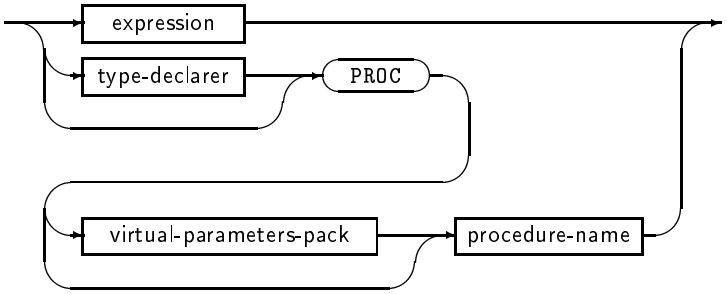


The primary must yield a procedure. The actual-parameters must agree in number and type with the formal-parameters of one of the definitions of that procedure.

The call is executed as follows: first its actual-parameters are evaluated collaterally; then its result is that of the body of that definition, after binding its formal parameters to the corresponding actual-parameters of the call. In case of a polymorphic procedure, its formal-type-names are implicitly bound (as synonyms) to the types of its actual-parameters.

Notice that a procedure without parameters is called by just mentioning its name, without parameters or brackets.

actual-parameter



5.4.5 Subscriptions

Elan has only one-dimensional arrays (rows) of a size (cardinality) fixed at compile time. A row can be subscripted to obtain one of its elements (which in its turn may be a row, a structure or a simple value). A multidimensional array can be realized as a row of rows.

subscription

The primary must yield a row. The expression must yield an integer, whose value lies between 1 and the cardinality of that row. The type of a subscription is the type of the element yielded. The subscription inherits the access-attribute of the primary. This implies that an assignation to a subscription is possible only if the primary is a variable.

5.4.6 Selections

A structure can be selected from, to obtain one of its fields (which in its turn may be a row, a structure or a simple value).

selection

The primary must yield a structure, one of whose fields has field-name as name. The type of the selection is the type of the field yielded. As is the case for the subscription, the selection inherits the access-attribute of its primary.

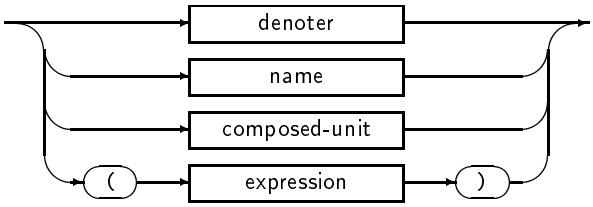
5.4.7 Abstractors

The abstractor serves to denote values of an abstract type. It will often be used together with a display, to abstract from a composed realization to an abstract object.

abstractor

The part after the colon (a compact-primary) must have the type of the realization of the abstract-type-name.

compact-primary



The value of an abstractor is the value of its compact-primary. The type of an abstractor is the type of the abstract-type-name, rather than its realization. Since the realization of a type is visible only in its defining packet, an abstractor with a specific abstract-type-name can only be used in the packet defining that abstract-type-name.

5.4.8 Concretizers

A concretizer serves to break the abstraction of a value.

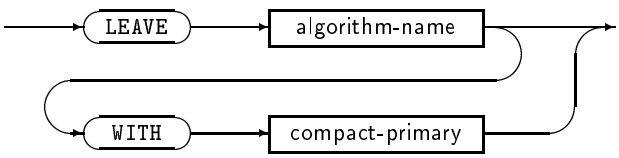
concretizer

The compact-primary must be of some abstract type; the concretizer is then of the type of its realization. It yields the value (which may be nil) of its compact-primary and inherits the access-attribute of its compact-primary. A concretizer can only be used in an environment where the realization of its abstract type is visible (5.2.1.3).

5.4.9 Terminators

A terminator serves to terminate the execution of a refinement, a procedure or an operator.

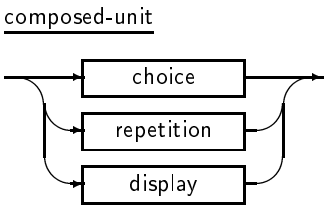
terminator



The algorithm-name must either be the name of the directly surrounding operator or procedure or of some visible refinement, of whose execution the terminator forms part. If a with-part is given, the algorithm named is terminated, yielding the value of the compact-primary, otherwise it is terminated yielding no value.

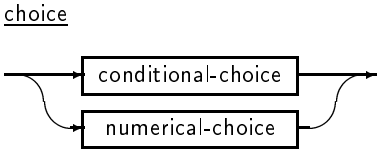
5.5 Control structures

The *control structures* of Elan are the choice, repetition and display. control structure



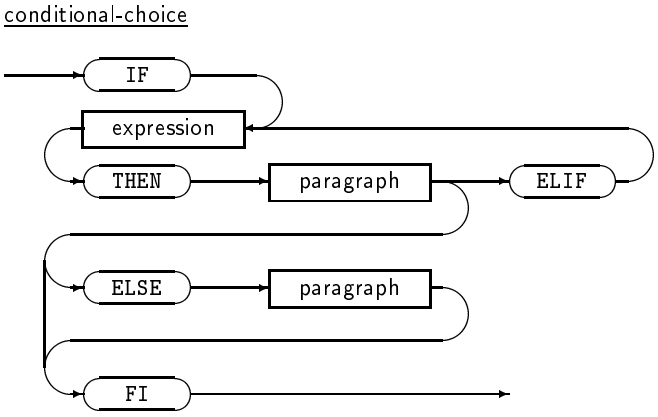
5.5.1 Choice

The choice is a construct for choosing between a number of alternative algorithms. There are two forms of choice.



5.5.1.1 Conditional-choice

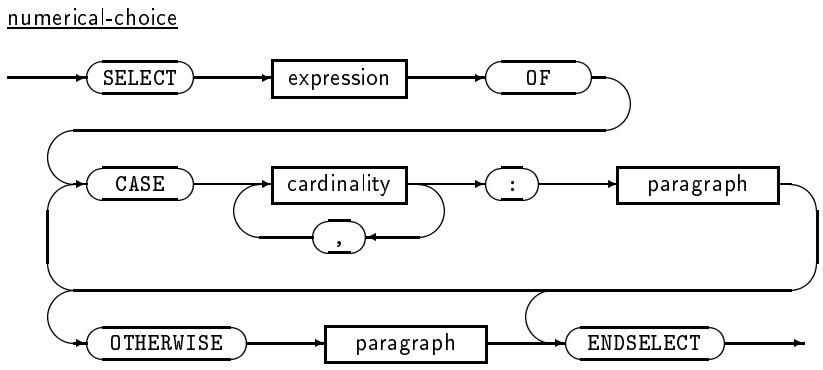
The conditional-choice chooses between two or more algorithms on the basis of one or more boolean expressions (*conditions*). condition



The result of the conditional-choice is that of the paragraph executed. Therefore all paragraphs in the conditional-choice must have the same type.

5.5.1.2 Numerical-choice

The numerical-choice is a somewhat baroque construct for choosing between a number of cases on the basis of an integer.

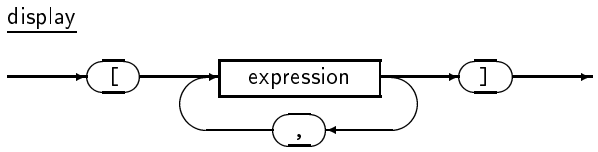


The cases must be labeled either with a number or with a synonym for a number, and therefore with a value fixed at compile-time. The labels of the cases must all be different and need not be ordered.

The numerical-choice is executed by first computing the value of the expression, which must yield an integer, and then executing the paragraph whose case label has that value, if any. If there is no paragraph labeled with this value, the otherwise-part (if any) is executed. The result of the numerical-choice is that of the paragraph executed. Therefore all paragraphs in the numerical-choice must have the same type.

5.5.2 Display

The display is a construct serving to denote values for composed types (structures and rows) and, in conjunction with the abstractor, for abstract types.



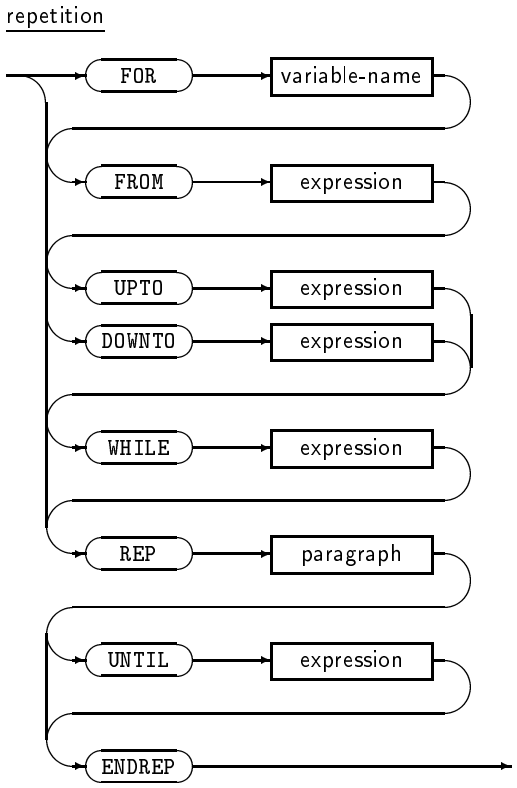
If the display is used to denote a row, the number of its constituent expressions has to be equal to the cardinality of the row, whereas each expression has to be of the type of the elements of the row.

If the display is used to denote a structure, the number of its constituent expressions has to be the same as the number of fields of the structure, whereas each expression has to be of the type of the corresponding field of the structure.

The display is executed by evaluating its constituent expressions collaterally, and composing a composed value from the values in their textual order. Its type is the type of that composed value, i.e. either a row or a structure, depending on the context.

5.5.3 Repetition

There is one, at first glance rather huge, construct which serves to express repetitions. Its purpose is to repeat a paragraph under various circumstances.



Since many of its constituents are optional, it can be tuned to different applications.

The expressions after `WHILE` and `UNTIL` are conditions, and therefore have to be boolean. The other expressions, as well as the variable after `FOR` (*controlled variable*) have to be integer. controlled variable

The semantics of the repetition is quite conventional. The for-part can be omitted if the controlled variable does not occur in the body of the repetition. The constituents `FROM 1`, `UPTO maxint`, `WHILE true` and `UNTIL false` can be omitted (i.e. are assumed if the corresponding constituents is omitted).

A repetition is an action.

5.5.4 Comments

Comments are remarks enclosed between comment-brackets, which have no influence on the execution of the program.

In the Elan Programming Environment, units may be alternated with comments. A comment starts with a comment-open-bracket and ends with a matching comment-close-bracket. Various representations for these brackets are available, as shown below, but the first one is preferred.

comment-open-bracket	matching comment-close-bracket

Chapter 6

Examples Elan subset

The following examples are intended to demonstrate specific Elan features, such as structures, procedures, operators and graphics facilities, as well as the definition of abstract data types by means of a packet.

6.1 Points and line segments

This section contains a packet for defining and drawing points and line segments in the *R2*. It uses straight integer-graphics (see A.7). In order to reduce complexity no clipping is performed. Drawing outside the (hardware-dependent) graphics-screen will result in distorted pictures. The packet should be read by means of the packet-command (`p`). The Elan Programming Environment can read packets but has no special precompilation facilities.

```
PACKET points and lines
DEFINES POINT, LINE,
        point, line, AS, *, +, =,
        draw point, draw line, put coord:

TYPE POINT = STRUCT (REAL x, y, TEXT name);

TYPE LINE = STRUCT (POINT a, b, TEXT name);

POINT PROC point (REAL x, y):
  # denotation-procedure for a point #
  POINT: [x, y, ""]
ENDPROC point;

POINT OP * (REAL factor, POINT point):
  POINT: [factor * point.x, factor * point.y, ""]
ENDOP *;

BOOL OP = (POINT point1, point2):
  point1.x = point2.x AND point1.y = point2.y
ENDOP =;

LINE PROC line (POINT point1, point2):
  # denotation-procedure for a line #
  LINE: [point1, point2, ""]
ENDPROC line;
```

```
LINE OP + (LINE line1, line2):
  assert (line1.b = line2.a, "lines not connected");
  LINE: [line1.a, line2.b, ""]
ENDOP +;

LINE OP * (REAL factor, LINE line):
  LINE: [factor * line.a, factor * line.b, ""]
ENDOP *;

BOOL OP = (LINE line1, line2):
  line1.a = line2.a AND line1.b = line2.b OR
  line1.a = line2.b AND line1.b = line2.a
ENDOP =;

POINT OP AS (POINT point, TEXT name):
  # giving a name to a point #
  POINT: [point.x, point.y, name]
ENDOP AS;

LINE OP AS (LINE line, TEXT name):
  # giving a name to a line #
  LINE: [line.a, line.b, name]
ENDOP AS;

PROC put coord (POINT point):
  # showing the name and coordinates of a point #
  IF NOT (point.name = "")
  THEN put (point.name + " = ");
  FI;
  put ("(" + text (point.x) + "," + text (point.y) + ")")
ENDPROC put coord;

PROC put coord (LINE line):
  # showing the name and coordinates of a line segment #
  IF NOT (line.name = "")
  THEN put (line.name + " = ");
  FI;
  put ("(" + text (line.a.x) + "," + text (line.a.y) + ")");
  put ("(" + text (line.b.x) + "," + text (line.b.y) + ")")
ENDPROC put coord;

PROC draw point (POINT point):
  # drawing a point and its name on the screen #
  move (int (point.x), int (point.y / aspect));
  plot pixel;
  put (point.name)
ENDPROC draw point;
```

```
PROC draw line (LINE line):
  # drawing a line and its name on the screen #
  INT x name :: int ((line.a.x + line.b.x) / 2.0),
      y name :: int ((line.a.y + line.b.y) / 2.0 / aspect),
      len :: length (line.name) * character width;
  draw point (line.a);
  draw point (line.b);
  move (x name, y name);
  put (line.name);
  move (x name, y name);
  draw (x name + len, y name);
  move (int (line.a.x), int (line.a.y / aspect));
  draw (int (line.b.x), int (line.b.y / aspect))
ENDPROC draw line;

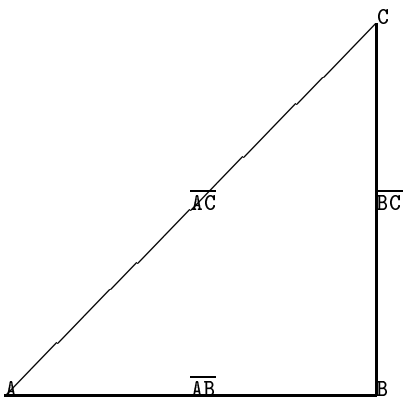
ENDPACKET points and lines;
```

6.2 Points and line segments example

This example demonstrates the use of the previous packet. It draws a triangle, annotating its points and sides with names. Note that the coordinates of `a`, `b` and `c` should be chosen to fit the screen of the particular computer (see A.7).

```
program:
  POINT a :: point (100.0, 400.0) AS "A",
        b :: point (400.0, 100.0) AS "B",
        c :: point (400.0, 400.0) AS "C";
  LINE ab :: line (a, b) AS "AB",
       bc :: line (b, c) AS "BC",
       ca :: ab + bc AS "AC";
  enter graphics mode;
  draw line (ab);
  draw line (bc);
  draw line (ca);
  TEXT VAR wait :: inchar;
  enter text mode.
```

The resulting picture looks like:



6.3 Intersection and projection

This section contains an addendum to the first packet. Procedures for finding the intersection of two lines and the projection of a point on a line are defined. Note that intersection of parallel lines will result in an error message.

```
POINT OP X (LINE line1, line2):
  calculate parameters;
  the intersection.

calculate parameters:
  REAL VAR rc1, b1, rc2, b2;
  BOOL vertical1 := (line1.a.x = line1.b.x);
  IF NOT vertical1
  THEN
    rc1 := (line1.a.y - line1.b.y) / (line1.a.x - line1.b.x);
    b1 := line1.a.y - rc1 * line1.a.x
  ELSE
    rc1 := maxreal
  FI;
  BOOL vertical2 := (line2.a.x = line2.b.x);
  IF NOT vertical2
  THEN
    rc2 := (line2.a.y - line2.b.y) / (line2.a.x - line2.b.x);
    b2 := line2.a.y - rc2 * line2.a.x
  ELSE
    rc2 := maxreal
  FI;
  assert (rc1 <> rc2, "intersection of two parallel lines").

the intersection:
  IF   vertical1
  THEN POINT: [line1.a.x, rc2 * line1.a.x + b2, ""]
  ELIF vertical2
  THEN POINT: [line2.a.x, rc1 * line2.a.x + b1, ""]
  ELSE POINT: [(b2 - b1) / (rc1 - rc2),
               (rc1 * b2 - b1 * rc2) / (rc1 - rc2),
               ""]
  FI.

ENDOP X;

POINT OP ON (POINT point, LINE line):
  calculate parameters;
  the projection.

calculate parameters:
  REAL VAR rc1, b1, rc2, b2;
  BOOL vertical :: (line.a.x = line.b.x),
       horizontal :: (line.a.y = line.b.y);
  IF NOT (horizontal OR vertical)
  THEN
    rc1 := (line.a.y - line.b.y) / (line.a.x - line.b.x);
    b1 := line.a.y - rc1 * line.a.x;
    rc2 := -1.0 / rc1;
    b2 := point.y - rc2 * point.x;
  FI.
```

```
  the projection:
    IF   horizontal
    THEN POINT: [point.x, line.a.y, ""]
    ELIF vertical
    THEN POINT: [line.a.x, point.y, ""]
    ELSE POINT: [(b2 - b1) / (rc1 - rc2),
                 (rc1 * b2 - b1 * rc2) / (rc1 - rc2),
                 ""]
    FI.

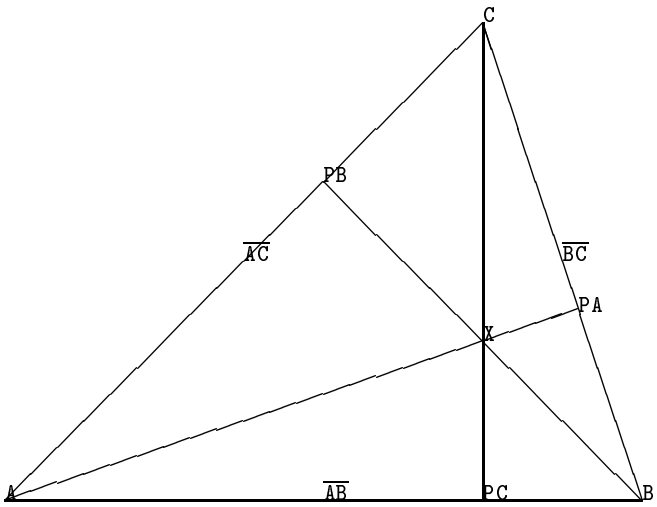
  ENDOP ON;
```

6.4 Intersection and projection example

This example demonstrates the use of the `X` (intersect) and `ON` (projection) operators. A triangle with its projection lines is drawn, showing the intersection of the three projection lines trough one point. Again, the coordinates of `a`, `b` and `c` should be judiciously chosen to fit the screen.

```
  program:
    POINT a :: point (100.0, 370.0) AS "A",
          b :: point (460.0, 370.0) AS "B",
          c :: point (370.0, 100.0) AS "C";
    LINE ab :: line (a, b) AS "AB",
         bc :: line (b, c) AS "BC",
         ca :: line (c, a) AS "AC";
    POINT a on bc :: (a ON bc) AS "PA",
          b on ca :: (b ON ca) AS "PB",
          c on ab :: (c ON ab) AS "PC";
    POINT x :: (line (c, c on ab) X line (a, a on bc)) AS "X";
    enter graphics mode;
    draw line (ab);
    draw line (bc);
    draw line (ca);
    draw line (line (a, a on bc));
    draw line (line (b, b on ca));
    draw line (line (c, c on ab));
    draw point (x);
    move (1, graphics y limit - 2 * line height);
    put coord (x);
    TEXT VAR wait :: inchar;
    enter text mode.
```

The resulting picture looks like:



```
X = ( 3.700000e+02, 2.800000e+02)
```

Further examples are included with the distributed software.

Appendix A

Standard library

A library of concrete algorithms, objects and types is available in Elan. Conceptually, they are declared in the "standard packets" which are presupposed for every execution. Version 1.7 of the Elan Programming Environment includes practically all standard packets (see [1]) apart from matrices and vectors, as well as a small number of extensions from the Elan-0 and EUMEL libraries. In this chapter the headings of all definitions in the library are listed. No attempt is made to explain their meaning, since this can be found in the Elan textbooks.

A.1 Integer

```
TYPE INT

PROC get (INT VAR i)
PROC put (INT CONST i)

BOOL OP = (INT CONST i1, i2)
BOOL OP <> (INT CONST i1, i2)
BOOL OP < (INT CONST i1, i2)

PROC write (INT CONST i)
PROC write (REAL CONST r)
PROC write (TEXT CONST t)
PROC write line

PROC read (INT VAR i)
PROC read (REAL VAR r)
PROC read (TEXT VAR t)

BOOL PROC file ended
```

A.6 Screen handling

```
PROC line
PROC line (INT CONST i)
PROC page
PROC beep

INT PROC xsize
INT PROC ysize
PROC cursor (INT CONST i1, i2)
PROC get cursor (INT VAR i1, i2)

PROC edit (TEXT VAR t, INT CONST start pos)
PROC edit (TEXT VAR t, INT CONST start pos, left margin,
           TEXT CONST end)
PROC edit (TEXT VAR t,
           INT CONST start pos, left margin, right margin,
           TEXT CONST end, TEXT VAR c)

PROC inchar (TEXT VAR t)
TEXT PROC inchar
TEXT PROC incharety
```

A.7 Graphics

```
INT PROC graphics x limit
INT PROC graphics y limit
REAL PROC aspect

PROC enter graphics mode
PROC enter text mode
BOOL PROC in text mode

PROC color (INT CONST i)
PROC clear graphics screen
```

```
INT PROC current x position
INT PROC current y position
PROC move (INT CONST x, y)
PROC draw (INT CONST x, y)
PROC plot pixel

PROC plot text (TEXT CONST t)
INT PROC character width
INT PROC line height
```

The console input-output routines are applicable also in graphics mode (example: `put`, `get`, `line`, `page`, `inchar`, `cursor`, `get cursor`,`xsize`, `ysize`, etc.).

A.8 Turtle-graphics

Turtle-graphics is not a part of the standard library, but a packet, which can be read into the Elan Programming Environment by means of the packet-command (`p`).

```
     enter turtle graphics
     leave turtle graphics
PROC turtle window (INT CONST xmin, xmax, ymin, ymax,
                    REAL CONST x range, y range)

PROC move (REAL CONST x, y)
PROC move (REAL CONST length)
PROC draw (REAL CONST length)

PROC turn (REAL CONST radian)
PROC turn (INT CONST angle)
PROC turn left
PROC turn right
```

A.9 Random numbers

```
PROC initialize random (INT CONST i)
PROC initialize random (REAL CONST r)

INT PROC random (INT CONST i1, i2)
PROC random (INT CONST i)
REAL PROC random
INT PROC choose128
```

A.10 Miscellaneous

```
BOOL OP ISNIL (NILTYPE CONST x)
BOOL PROC isnil (NILTYPE CONST x)

BOOL PROC last conversion ok

BOOL PROC yes (TEXT CONST question)
BOOL PROC no (TEXT CONST question)

INT PROC freespace
INT PROC exectime
PROC sleep (INT CONST seconds)
```

```
PROC trace on
PROC stop
PROC assert (BOOL CONST b)
PROC assert (BOOL CONST b, TEXT CONST t)
```

Note: there are some other routines in the standard library not mentioned in the above list, but those are for internal use within the library, therefore we strongly advise against using them.

Appendix B

Ascii-table

The Elan interpreter uses a slightly modified ASCII code.

	0	1	2	3	4	5	6	7
0	nul			0	@	P		p
1	cls		!	1	A	Q	a	q
2	cll		"	2	B	R	b	r
3	brk		#	3	C	S	c	s
4	del		$	4	D	T	d	t
5	right		%	5	E	U	e	u
6	left		&	6	F	V	f	v
7	bel		‘	7	G	W	g	w
8	up		(	8	H	X	h	x
9	down	brk	)	9	I	Y	i	y
A	lf		*	:	J	Z	j	z
B			+	;	K	[	k	{
C			’	<	L		l	|
D	cr		-	=	M	]	m	}
E			.	>	N	^	n	
F			/	?	O	’	o	

The control characters have the following meanings:

`nul`	null character
`cls`	clear the screen
`cll`	clear to end of line
`del`	delete character under cursor
`right`	cursor right
`left`	cursor left
`up`	cursor up
`down`	cursor down
`bel`	produce the bell-sound
`lf`	line feed
`cr`	carriage return
`brk`	break
